About the Authors

Photo credit: John Soares

HARVEY LODISH is Professor of Biology and Professor of Biological Engineering at the Massachusetts Institute of Technology and a Founding Member of the Whitehead Institute for Biomedical Research. Dr. Lodish is also a member of the National Academy of Sciences and the American Academy of Arts and Sciences and was President (2004) of the American Society for Cell Biology. He is well known for his work on cell-membrane physiology, particularly the biosynthesis of many cell-surface proteins, and on the cloning and functional analysis of several cell-surface receptor proteins, such as the erythropoietin and TGF-β receptors. His laboratory also studies long noncoding RNAs and micro-RNAs that regulate the development and function of hematopoietic cells and adipocytes.

Dr. Lodish teaches undergraduate and graduate courses in cell biology and biotechnology.

ARNOLD BERK holds the UCLA Presidential Chair in Molecular Cell Biology in the Department of Microbiology, Immunology, and Molecular Genetics and is a member of the Molecular Biology Institute at the University of California, Los Angeles. Dr. Berk is also a fellow of the American Academy of Arts and Sciences. He is one of the discoverers of RNA splicing and of mechanisms for gene control in viruses. His laboratory studies the molecular interactions that regulate transcription initiation in mammalian cells, focusing in particular on adenovirus regulatory proteins. He teaches an advanced undergraduate course in cell biology of the nucleus and a graduate course in the biochemistry of gene expression.

Photo credit: Chris Kaiser

CHRIS A. KAISER is the Amgen Inc. Professor in the Department of Biology at the Massachusetts Institute of Technology. He is also a former Department Head and former Provost at MIT. His laboratory uses genetic and cell biological methods to understand how newly synthesized membrane and secretory proteins are folded and stored in the compartments of the secretory pathway. Dr. Kaiser is recognized as a top educator at MIT, where he has taught genetics to undergraduate and graduate students for many years.

Photo credit: Monty Krieger

MONTY KRIEGER is the Whitehead Professor in the Department of Biology at the Massachusetts Institute of Technology and a Senior Associate Member of the Broad Institute of MIT and Harvard. Dr. Krieger is also a member of the National Academy of Sciences. For his innovative teaching of undergraduate biology and human physiology as well as graduate cell biology courses, he has received numerous awards. His laboratory has made contributions to our understanding of membrane trafficking through the Golgi apparatus and has cloned and characterized receptor proteins important for pathogen recognition and the movement of cholesterol into and out of cells, including the HDL receptor.

Photo credit: Anthony Bretscher

ANTHONY BRETSCHER is Professor of Cell Biology at Cornell University and a member of the Weill Institute for Cell and Molecular Biology. His laboratory is well known for identifying and characterizing new components of the actin cytoskeleton and elucidating their biological functions in relation to cell polarity and membrane traffic. For this work, his laboratory exploits biochemical, genetic, and cell biological approaches in two model systems, vertebrate epithelial cells and the budding yeast. He is a fellow of the American Academy of Arts and Sciences. Dr. Bretscher teaches cell biology to undergraduates at Cornell University.

Photo credit: Hidde Ploegh

HIDDE PLOEGH is a senior investigator in the Program of Cellular and Molecular Medicine at Boston Children's Hospital, where he studies the biochemistry of the immune system. A member of the National Academy of Science and the American Academy of Arts and Sciences, he is one of the world's leading researchers in the molecular understanding of immune system cells and the mechanisms by which viruses evade detection by the immune system. Prior to his current position he was a professor at the Massachusetts Institute of Technology and Harvard Medical School, where he taught immunology and cell biology.

Photo credit: Phuong Pham

KELSEY C. MARTIN is Professor of Biological Chemistry and Psychiatry and Dean of the David Geffen School of Medicine at the University of California, Los Angeles. She is the former Chair of the Biological Chemistry Department. Her laboratory studies the ways in which experience changes connections between neurons in the brain to store long-term memories — a process known as *synaptic plasticity*. She has made important contributions to elucidating the molecular and cell biological mechanisms that underlie this process. Dr. Martin teaches basic principles of neuroscience to undergraduates, graduate students, dental students, and medical students.

Photo credit: Michael B. Yaffe, Koch Institute for Integrative Cancer Research

MICHAEL B. YAFFE is the David H. Koch Professor of Science in the Departments of Biology and Biological Engineering at the Massachusetts Institute of Technology and a Senior Associate Member of the Broad Institute of MIT and Harvard. He is also the Academic Editor-in-Chief of the journal *Science Signaling*. His laboratory studies the cellular response to stress and injury, and is well known for the discovery and characterization of modular protein domains and protein kinases that form molecular signaling circuits. Dr. Yaffe teaches undergraduate biochemistry and graduate cell biology courses, for which he has received numerous awards. He also instructs medical students and residents in the intensive care unit at the Beth Israel Deaconess Medical Center, where he is an attending physician.

Photo credit: Pamela DiFraia/Koch Institute/MIT

ANGELIKA AMON is Professor of Biology at the Massachusetts Institute of Technology, a member of the Koch Institute for Integrative Cancer Research, and Investigator at the Howard Hughes Medical Institute. She is also a member of the National Academy of Sciences. Her laboratory studies the molecular mechanisms that govern chromosome segregation during mitosis and meiosis and the consequences — aneuploidy — when these mechanisms fail during normal cell proliferation and cancer development. Dr. Amon teaches undergraduate and graduate courses in cell biology and genetics.

The authoritative cell biology resource, now available with Achieve

Molecular Cell Biology remains the most authoritative cell biology textbook. The ninth edition is now available in Macmillan's new online learning platform, **Achieve**. The author team, consisting of world-class researchers and professors, has incorporated numerous medically relevant examples to illustrate connections between cell biology and human health and disease. Experimental techniques that drive advances in biomedical sciences are emphasized, introducing students to cutting-edge research that teaches them the skills they need for their careers.

Overview of key features

The ninth edition of ***Molecular Cell Biology*** is now available in **Achieve**. Achieve supports educators and students throughout the full range of instruction, including assets suitable for pre-class preparation, in-class active learning, and post-class study and assessment. The pairing of a powerful new platform with

outstanding biology content provides an unrivaled learning experience.

FEATURES OF ACHIEVE INCLUDE

- A **design guided by learning science research**. Developed with extensive collaboration and testing by students and faculty, including two levels of Institutional Review Board approval for every efficacy study of Achieve.
- A **learning path** of powerful content including pre-class, in-class, and post-class activities and assessments.
- A **detailed gradebook with insights for just-in-time teaching** and reporting on student achievement by learning concept.
- Easy **integration and gradebook synchronization with iClicker** classroom engagement solutions.
- Simple **integration with your campus LMS** and **availability through Inclusive Access** programs.

NEW MEDIA AND ASSESSMENT FEATURES IN ACHIEVE INCLUDE

- Five new **in-class activities**, along with revised **classroom response questions** support an active and inclusive classroom.
- **LearningCurve adaptive quizzing** provides formative assessments to help students prepare before class.
- **Case Studies** and **Analyze the Data Problems** focus on real-world applications.

- **Chapter Concept Quizzes** provide easy to assign and automatically graded assessments.

FEATURES OF THE TEXT INCLUDE

- The text and figures **emphasize the experiments** that define our understanding of cell biology, engaging students with the exciting breakthroughs that define the field's history and point to its future.
- **Experimental Figures** illustrate important techniques and experiments and show real data.
- **Medical Connections** are woven throughout the chapters to give students an appreciation for the clinical applications of the basic science they are learning.
- In many chapters, **Plant Biology Connections** spotlight plant biotechnology and unique aspects of cell biology in plants.
- **Key Concepts** for each section provide a learning framework for students as they progress through a chapter.

Achieve

Achieve is the culmination of years of development work put toward creating the most powerful online learning tool for biology students. It houses all of our renowned assessments, multimedia assets, e-books, and instructor resources in a powerful new platform.

Achieve supports educators and students throughout the full range of instruction, including assets suitable for pre-class preparation, in-class active learning, and post-class study and assessment. The pairing of a powerful new platform with outstanding biology content provides an unrivaled learning experience.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

Highlights include:

- **A design guided by learning science research.** Co-designed through extensive collaboration and testing by both students and faculty including two levels of Institutional Review Board approval for every study of Achieve.
- **A learning path of powerful content** including pre-class, in-class, and post-class activities and assessments. A detailed gradebook with insights for just-in-time teaching and reporting on student achievement by learning objective.
- **Easy integration and gradebook sync** with iClicker classroom engagement solutions.
- **Simple integration** with your campus LMS and availability through **Inclusive Access** programs.

For more information or to sign up for a demonstration of Achieve, contact your local Macmillan representative or visit macmillanlearning.com/achieve.

Full Learning Path

Achieve includes a full learning path of content for pre-class preparation, in-class active learning, and post-class engagement and assessment. It's the perfect solution for engaging all students in an inclusive teaching experience.

LearningCurve

LearningCurve's game-like quizzing motivates each student to engage with the course content, and reporting tools help teachers get a handle on what their class needs.

Book-specific quizzes adapt their level of difficulty based on individual student performance.

Students earn points for correct answers . . . and receive immediate feedback on incorrect answers.

Questions are tagged to sections of the e-book to provide comprehensive coverage and easy-to-find help.

Upon completion, each student receives a study plan with links to additional study tools.

Quiz adapts to each student's needs based on performance, automatically providing more questions on topics where the student is struggling.

Performance by Learning Objectives can also be tracked to give instructors actionable information about topics that need extra emphasis.

In-Class Activities

Active learning exercises provide students with hands-on exploration and help correct common misconceptions.

The activities have been vetted in the classroom and serve as a great off-the-shelf option for incorporating new methods of active learning in your classroom.

The activities include everything you need, including an instructor's guide, presentation decks, and student handouts.

iClicker

Achieve includes gradebook integration with iClicker, allowing for a seamless pairing of the best classroom response system with the best in-class content.

Powerful analytics, viewable in an elegant dashboard, offer instructors a window into student progress. Achieve gives you

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

the insight to address students' weaknesses and misconceptions before they struggle on a test.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

A text grounded in experimentation and research

Molecular Cell Biology **emphasizes the experiments** that define our understanding of cell biology, engaging students with the exciting breakthroughs that define the field's history and point to its future.

There is a good balance between the experimental evidence and the concepts. Many times if a student can understand how the information was gained, it helps them understand the material.

— Jamie Snyder, *California State Polytechnic University, Pomona*

transfer to later compartments can be followed over time. Second, it is necessary to have a way to identify the compartment in which a labeled protein resides. Here we describe two modern experimental procedures for observing the intracellular trafficking of a secretory protein in almost any type of cell.

In both procedures, a gene encoding an abundant membrane glycoprotein (G protein) from vesicular stomatitis virus (VSV) is introduced into cultured mammalian cells either by transfection or simply by infecting the cells with the virus. The transfected cells efficiently produce the VSV G protein, which is then inserted into the membrane of the ER. The use of a mutant gene encoding a temperature-sensitive VSV G protein allows researchers to turn subsequent transport of this protein on and off. At the restrictive temperature of 40 °C, newly made VSV G protein is misfolded and therefore retained within the ER by the quality-control mechanisms discussed in Chapter 13, whereas at the permissive temperature of 32 °C, the protein is correctly folded and transported through the secretory pathway to the cell surface. Importantly, the misfolding of the temperature-sensitive VSV G protein is reversible; thus when cells synthesizing mutant VSV G protein are grown at 40 °C and then shifted to 32 °C, the misfolded mutant VSV G protein that had accumulated in the ER will refold and be transported normally. This clever use of a temperature-sensitive mutation in effect defines a protein cohort whose subsequent transport can be followed.

In two variations of this basic procedure, transport of VSV G protein is monitored by different techniques. Studies using both of these modern trafficking assays came to the same conclusion as Palade's early experiments: in mammalian cells, vesicle-mediated transport of a protein molecule from its site of synthesis on the rough ER to its arrival at the plasma membrane takes from 30 to 60 minutes.

Microscopy of GFP-Labeled VSV G Protein One approach for observing the transport of VSV G protein employs a hybrid gene in which the viral gene is fused to the gene encoding green fluorescent protein (GFP), a naturally occurring fluorescent protein (see Chapter 4). The hybrid gene is transfected into cultured cells by techniques described in Chapter 6. When cells expressing the temperature-sensitive form of the hybrid protein (VSVG-GFP) are grown at the restrictive temperature, VSVG-GFP accumulates in the ER, which appears as a lacy network of membranes when the cells are observed in a fluorescent microscope. When the cells are subsequently shifted to a permissive temperature, the VSVG-GFP can be seen to move first to the membranes of the Golgi complex, which are densely concentrated at the edge of the nucleus, and then to the cell surface (Figure 14-3a). By observing the distribution of VSVG-GFP at different times after shifting cells to the permissive temperature, researchers have determined how long VSVG-GFP resides in each organelle of the secretory pathway (Figure 14-3b).

Detection of Compartment-Specific Oligosaccharide Modifications A second way to follow the transport of secretory proteins takes advantage of modifications to their carbohydrate side chains that occur at different stages of the secretory pathway. To understand this approach, recall that many secretory proteins leaving the ER are carrying one or more copies of the *N*-linked oligosaccharide $Man_8(GlcNAc)_2$, which are synthesized and attached to secretory proteins in the ER (see Figure 13-18). As a protein moves through the Golgi complex, different enzymes localized to the *cis*-, *medial*-, and *trans*-Golgi cisternae catalyze an ordered series of modifications to these core $Man_8(GlcNAc)_2$ chains, as discussed in a later section of this chapter. For instance, glycosidases that reside specifically in the *cis*-Golgi compartment

EXPERIMENTAL FIGURE 14-3 Protein transport through the secretory pathway can be visualized by fluorescence microscopy of cells producing a GFP-tagged membrane protein. Cultured cells were transfected with a hybrid gene encoding the viral membrane glycoprotein VSV G linked to the gene for green fluorescent protein (GFP). A temperature-sensitive mutant version of the viral gene was used so that newly made hybrid protein (VSVG-GFP) was retained in the ER at 40 °C but was released for transport at 32 °C. (a) Fluorescence micrographs of cells just before and at two times after they were shifted to the lower temperature. Movement of VSVG-GFP from the ER to the Golgi and finally to the cell surface occurred within 180 minutes. The scale bar is 5 μm. (b) Plot of the amount of VSVG-GFP in the endoplasmic reticulum (ER), Golgi, and plasma membrane (PM) at different times after the shift to the permissive temperature. The kinetics of transport from one organelle to another can be reconstructed from computer analysis of these data. The decrease in total fluorescence that occurs at later times probably results from slow inactivation of GFP fluorescence. [Jennifer Lippincott-Schwartz and Koret Hirschberg, Metabolism Branch, National Institute of Child Health and Human Development.]

Relevant connections for students

Medical Connections are woven throughout the chapters to give students an appreciation for the clinical applications of the basic science they are learning.

FIGURE 7-19 Exon shuffling by transposition. (a) Transposition of an exon flanked by homologous DNA transposons into an intron on a second gene. As we saw in Figure 7-10, step 1, transposase can recognize and cleave the DNA at the ends of the transposon inverted repeats. In gene 1, if the transposase cleaves at the left end of the transposon on the left and at the right end of the transposon on the right, it can transpose all the intervening DNA, including the exon from gene 1, to a new site in an intron of gene 2. The net result is an insertion of the exon from gene 1 into gene 2. (b) Integration of an exon into another gene via LINE transposition. Some LINEs have weak poly(A) signals. If such a LINE is in the 3′-most intron of gene 1, during transposition its transcription may continue beyond its own poly(A) signals and extend into the 3′ exon, transcribing the cleavage and polyadenylation signals of gene 1 itself. This RNA can then be reverse-transcribed and integrated by the LINE ORF2 protein (see Figure 7-17) into an intron on gene 2, introducing a new 3′ exon (from gene 1) into gene 2.

combined effects of several enhancer elements. Insertion of mobile elements near such transcription-control regions probably contributed to the evolution of new combinations of enhancer sequences. These combinations, in turn, control which specific genes are expressed in particular cell types and the amount of the encoded protein produced in modern organisms, as we discuss in the next chapter.

These considerations suggest that the early view of mobile DNA elements as completely selfish molecular parasites misses the mark. Rather, these elements have contributed profoundly to the evolution of multicellular organisms by promoting (1) the generation of gene families via gene duplication, (2) the creation of new genes via shuffling of preexisting exons, and (3) the formation of more complex regulatory regions that provide multifaceted control of gene expression. Today researchers are attempting to harness transposition mechanisms to insert therapeutic genes into patients as a form of gene therapy.

A process analogous to that shown in Figure 7-19a is largely responsible for the rapid spread of antibiotic resistance among pathogenic bacteria, a major problem in modern medicine. Bacterial genes encoding enzymes that inactivate antibiotics (drug resistance genes) have become flanked by insertion sequences, generating drug resistance transposons. The widespread use of antibiotics in medicine and agriculture has led to positive selection on drug resistance transposons. These transposons are often found incorporated into conjugating plasmids. Conjugating plasmids encode proteins that result in their replication and transfer to other bacterial cells—even cells of other related bacterial species—through a complex macromolecular tube called a pilus. These plasmids, called *R factors* (for drug resistance), can carry multiple drug resistance genes introduced by transposition and selected in environments, such as hospitals, where antibiotic-laced cleaning solutions are used to sterilize surfaces. R factors have led to the rapid spread of resistance to multiple antibiotics among pathogenic bacteria. Coping with the spread of R factors is a major challenge for modern medicine. ■

FIGURE 17-37 Cytoplasmic streaming in cylindrical giant algae. (a) Cells of *Nitella*, a freshwater alga commonly found in ponds in the summer. The cytoplasmic movement, described below, can be readily observed with a simple microscope, so go find some *Nitella* (or related algae) and watch this amazing phenomenon! (b) The center of a *Nitella* cell is filled with a single large water-filled vacuole, which is surrounded by a layer of moving cytoplasm (blue arrows). A nonmoving layer of cortical cytoplasm filled with chloroplasts lies just under the plasma membrane (enlarged in bottom figure). On the inner side of this layer are bundles of stationary actin filaments (red), all oriented with the same polarity. A motor protein (blue), a plant myosin V, carries parts of the endoplasmic reticulum (ER) along the actin filaments. The movement of the ER network propels the entire viscous cytoplasm, including organelles that are enmeshed in the ER network. (c) Electron micrograph of the cortical cytoplasm showing a large vesicle connected to an underlying bundle of actin filaments. [Part (c) Courtesy Bechara Kachar.]

so contraction is slower in smooth muscle than in skeletal muscle. Because this regulation involves myosin, it is known as *thick-filament regulation*.

Unlike skeletal muscle, which is stimulated to contract solely by nerve impulses, smooth muscle cells and nonmuscle cells are regulated by many types of external signals. For example, norepinephrine, angiotensin, endothelin, histamine, and other signaling molecules modulate or induce the contraction of smooth muscle or elicit changes in the shape and adhesion of nonmuscle cells by triggering various signal transduction pathways. Some of these pathways lead to an increase in the cytosolic Ca^{2+} concentration, which can stimulate myosin activity by activating MLC kinase (see Figure 17-35). As we will see in Section 17.7, other signaling pathways activate *Rho kinase*, which also activates myosin activity by phosphorylating the regulatory light chain, but in a Ca^{2+}-independent manner.

Perhaps the most dramatic example of movement by myosin V is seen in giant green algae, such as *Nitella* and *Chara*. These algae can be found in ponds during the summer and their movement easily observed using a simple microscope. In their large cells, which can be as much as 2 cm in length, cytosol flows rapidly, at a rate approaching 4.5 mm per minute, in an endless loop around the inner circumference of the cell (Figure 17-37). This *cytoplasmic streaming* is a principal mechanism for distributing cellular metabolites and is also seen in other large cells such as plant cells and amoebae. The algal cells have bundles of actin filaments aligned along the length of the cell, lying just above the stationary chloroplasts located adjacent to the membrane. The bulk cytosol is propelled by myosin V (also known as *myosin XI* in plants) attached to parts of the ER adjacent to the actin filaments. The flow rate of the cytosol in *Nitella* is about 15 times faster than movement produced by any other myosins. ■

Plant Biology Connections spotlight plant biotechnology and unique aspects of cell biology in plants.

"

I love the many great medical examples highlighted explicitly by "medical icons," including Ras in oncogenic transformation, HER2 in breast cancer, "bubble boy," etc. I have a lot of premed students who take my Cell Bio class, and they would love this.

— Adam Bohnert, *Louisiana State University*

Preface

In writing the ninth edition of *Molecular Cell Biology*, we have incorporated many of the spectacular advances made over the past four years in biomedical science, driven in part by new experimental technologies that have revolutionized many fields. Fast techniques for sequencing DNA, allied with efficient methods to generate and study mutations in model organisms and to map disease-causing mutations in humans, have illuminated a basic understanding of the functions of many cellular components, including hundreds of human genes that affect diseases such as diabetes and cancer.

Exploring the most current developments in the field is always a priority in writing a new edition, but it is also important to us to communicate the basics of cell biology clearly by stripping away as much extraneous detail as possible to focus attention on the fundamental concepts of cell biology. To this end, in addition to introducing new discoveries and technologies, we have streamlined and reorganized several chapters to clarify processes and concepts for students.

New Co-Author, Michael B. Yaffe

The ninth edition of *Molecular Cell Biology* introduces a new member to our author team. Dr. Yaffe is the David H. Koch Professor of Science in the Departments of Biology and Biological Engineering at the Massachusetts Institute of Technology and a Senior Associate Member of the Broad Institute of MIT and Harvard. He is also the Academic Editor-in-Chief of the journal *Science Signaling*. His laboratory studies the cellular response to stress and injury and is well known for the discovery and characterization of modular protein domains and protein kinases that form molecular signaling circuits. Dr. Yaffe teaches undergraduate biochemistry and graduate cell biology courses, for which he has received numerous awards. He also instructs medical students and residents in the intensive care unit at the Beth Israel Deaconess Medical Center, where he is an attending physician.

Revised, Cutting-Edge Content

The ninth edition of *Molecular Cell Biology* includes new and improved chapters:

- "Fundamental Molecular Genetic Mechanisms" (Chapter 5) has been reorganized to begin with the structure and replication of DNA, followed by DNA repair and recombination. A new discussion of the information-carrying capacity of DNA has been added, as well as using the genetic code to predict the effect of mutations.

- “Genes, Chromatin, and Chromosomes” (Chapter 7) has been renamed to reflect our much greater understanding of the roles chromatin plays in gene expression. Section 7.4 provides details of the molecular differences between euchromatin and heterochromatin, the processes that occur as regions of chromatin shift from one form to the other, and the protein modifications and signaling pathways that cause these shifts to occur.
- “Biomembrane Structure” (Chapter 10) has been moved later in Part II of the book (previously Chapter 7) to directly precede “Transmembrane Transport of Ions and Small Molecules” and refine the progression of Part II.
- “Cellular Energetics” (Chapter 12) has been revised to approach energetics from the conceptual point of optimizing output. New discussions have been added on intra- and intercellular mitochondrial movements as well as membrane contact sites (MCSs).
- “The Eukaryotic Cell Cycle” (Chapter 19) now opens with an overview of the cell cycle that is presented in a story-like manner, outlining the flow from G_1 phase around the cycle to M phase and back into G_1. Section 19.3 presents our latest understanding about feedback loops and protein modifications that control the cell cycle. Figures have been extensively revised and many new figures have been added, providing overviews of the tiered regulatory processes that control cyclin-dependent kinases and showing clearly how protein complexes perform the many carefully controlled steps of the cell cycle.

- "Responding to the Cellular Environment" (Chapter 21) is a new chapter. It covers many important signaling pathways by which cells respond to changes of nutrients in their environment — glucose, amino acids, cholesterol, and oxygen — as well as to changes in temperature and contact with the extracellular matrix and other cells. Circadian rhythms are also covered.

New Discoveries, New Methodologies

- *Schizosaccharomyces pombe* (cell cycle control) (Ch. 1)
- Neanderthal evolution and genomics (Ch. 1)
- Single-cell RNA sequencing and identification of new types of cells (Chs. 1 and 6)
- Increased focus on regulation of protein activity (Ch. 3)
- Increased coverage of kinases: family tree, kinase structure, and regulation (Ch. 3)
- Recent breakthroughs in protein structure prediction (Ch. 3)
- Biomolecular condensates, including methods to study and identify them (Ch. 3)
- Updated mechanisms and functions of chaperones and proteasomes (Ch. 3)
- iTRAQ and TMT methods for simultaneous, multiplex analysis of samples (Ch. 3)
- Updated resolution of cryoEM (Ch. 3)
- Use of enzyme-catalyzed, proximity-dependent labeling coupled with mass spectrometry for localization of proteins in cells (Ch. 3)
- Generation and use of organoids (Ch. 4)

- Use of optogenetics (Ch. 4)
- New discussion of information-carrying capacity of DNA (Ch. 5)
- New discussion of reading genetic code in predicting the effect of mutations (Ch. 5)
- New discussion of methylation in distinguishing parent and daughter strands (Ch. 5)
- New section on global analysis of double mutant combinations that reveal networks of gene functions (Ch. 6)
- Expanded discussion of cDNA libraries and their limitations (Ch. 6)
- New section on medically important genes identified by alleles that protect against disease (Ch. 6)
- New section on identification of causative mutations in cancer cells (Ch. 6)
- Updated discussion of CRISPR-Cas genome editing (Ch. 6)
- Revised section on chromatin structure (Ch. 7)
- New section on chromatin packing in the nucleus and updated information about SMC protein complexes' role in chromatin compaction (Ch. 7)
- Cryoelectron microscopy models of the preinitiation complex (Ch. 8)
- New section on transcriptional condensates (Ch. 8)
- New section on transcription occurring in bursts (Ch. 8)
- Updated discussion of spliceosome (Ch. 9)
- New section on abnormal RNA splicing and disease (Ch. 9)
- Expanded and updated discussion of V-class proton pumps (Ch. 11)
- Updated discussion of K^+ channels (Ch. 11)

- Expanded discussion on bacterial Na^+ galactose symporter (Ch. 11)
- Expanded discussion of Anion Exchanger 1 (Ch. 11)
- New and updated discussion of mitochondrial structure and dynamics (e.g., fusion and fission) based on state-of-the-art super-resolution microscopy (e.g., grazing incidence-structured illumination microscopy) (Ch. 12)
- Updates on relationship of mitochondria to Parkinson's disease (Ch. 12)
- New discussion of membrane contact sites (Ch. 12)
- Updated discussion of structure of electron-transport chain supercomplexes (Ch. 12)
- Reorganized and updated coverage of photosynthesis (Ch. 12)
- Updated discussion on mechanisms that protect cells from damage by reactive oxygen species, such as singlet oxygen, during photoelectron transport (Ch. 12)
- Families of human G protein–coupled receptors (Ch. 15)
- Gene therapy to correct a form of human blindness (Ch. 15)
- Structure and activation of the insulin receptor (Ch. 16)
- Interleukin 2 (IL-2) receptors and gene therapy to correct severe combined immune deficiency (Ch. 16)
- Molecular structure of gamma secretase (Ch. 16)
- Giant cell-surface signalsomes (Ch. 16)
- New description of microtubule nucleator augmin (Ch. 18)
- New section on spindle positioning during mitosis (Ch. 18)
- New section on regulation of the contractile ring during cytokinesis (Ch. 18)

- New sections on cyclin discovery and cyclin-CDK regulation (Ch. 19)
- Thiol-labeled γ phosphate-based approaches to identify CDK substrates with genetic engineering (Ch. 19)
- Updated discussion of SCF ubiquitin ligases and the anaphase-promoting complex (Ch. 19)
- New sections on how feedback loops and phosphoserine/threonine-binding domains control the cell cycle (Ch. 19)
- Expanded discussion of Aurora and Polo-like kinases (Ch. 19)
- New section on centrosome duplication (Ch. 19)
- Extensive updated coverage of cytokinesis (Ch. 19)
- Updated discussion of DNA damage and cell cycle surveillance (Ch. 19)
- Protocadherin mechanism of adhesion and role in bar-coding neurons (Ch. 20)
- Updated discussion of mechanotransduction (Ch. 20)
- Updated discussion of integrin activation, including new discussion of three conformation models (Ch. 20)
- Mechanism of talin-mediated inside-out and outside-in signaling and mechanotransduction (Ch. 20)
- Updated discussion of O-linked glycoproteins and O-mannose linked oligosaccharides (Ch. 20)
- Updated discussion of claudin-mediated paracellular transport (Ch. 20)
- Updated discussion of plant plasmodesmata structure and composition (Ch. 20)

- New section on biomolecular condensates and adhesion (Ch. 20)
- Extensive updates on plant adhesion molecules and mechanotransduction (Ch. 20)
- Updated and expanded discussion of mTOR pathway and integration of cell growth signals with nutrient and energy levels (Ch. 21)
- New section on HIF-1α and the response of cells to low oxygen levels (Ch. 21)
- New section on the heat-shock response (Ch. 21)
- New section on circadian rhythms (Ch. 21)
- Updated and expanded discussion of mechanotransduction (Ch. 21)
- Updated and expanded discussion of cells in intestinal crypts that dedifferentiate to replenish intestinal stem cells (Ch. 22)
- Updated discussion of Cdc42 and feedback loops that control cell polarity (Ch. 22)
- New section on “eat me” phosphatidylserine signals on apoptotic cells (Ch. 22)
- Updated discussion of necroptosis, an inflammatory form of programmed cell death (Ch. 22)
- Multiple revised figures to clearly demonstrate neurons and neural structures (Ch. 23)
- Expanded discussion of the blood-brain barrier (Ch. 23)
- New discussion of Piezo1 and Piezo2 receptors (Ch. 23)
- New section on natural killer (NK) cells, now called *ILCs* (Ch. 24)

- New discussion of herd immunity and the benefits of childhood vaccinations (Ch. 24)
- New section on immunotherapies in the treatment of cancer (Ch. 25)
- Updated discussion of cancer genome sequencing (Ch. 25)

Medical Connections

Many advances in basic cellular and molecular biology have led to new treatments for cancer and other human diseases. Examples of such medical advances are woven throughout the chapters to give students an appreciation for the clinical applications of the basic science they are learning. Many of these applications hinge on a detailed understanding of multiprotein complexes in cells — complexes that catalyze cell movements; regulate DNA transcription, replication, and repair; coordinate metabolism; and connect cells to other cells and to proteins and carbohydrates in their extracellular environment.

- Stereoisomers of small molecules as drugs — sterically pure molecules have different effects from mixtures (Ch. 2)
- Cholesterol is hydrophobic and must be transported by lipoprotein carriers LDL and HDL (Ch. 2)
- Essential amino acids must be provided in livestock feed (Ch. 2)
- Saturated, unsaturated, and trans fats: their molecular structures and nutritional consequences (Ch. 2)
- Protein misfolding and amyloids in neurodegenerative diseases such as Alzheimer's and Parkinson's (Ch. 3)

- Small molecules that inhibit enzyme activity can be used as drugs (aspirin) or in chemical warfare (sarin gas) (Ch. 3)
- Small-molecule inhibitors of the proteasome are used to treat certain cancers (Ch. 3)
- Disruptions of GTPases, GAPs, GEFs, and GDIs by mutations and pathogens cause a wide variety of diseases (Ch. 3)
- 3-D printing technology may be used to grow replacement organs (Ch. 4)
- Monoclonal antibodies can be used as diagnostic and therapeutic tools in medicine (Ch. 4)
- Mutations in mismatch repair proteins lead to hereditary nonpolyposis colorectal cancer (Ch. 5)
- Nucleotide excision-repair proteins were identified in patients with xeroderma pigmentosum (Ch. 5)
- The high-resolution structures of ribosomes are used in the design of new antibiotics (Ch. 5)
- The sickle-cell allele is an example of one that exhibits both dominant and recessive properties depending on the phenotype being examined (Ch. 6)
- DNA microarrays can be useful as medical diagnostic tools (Ch. 6)
- Recombinant DNA techniques are used to mass-produce therapeutically useful proteins such as insulin and G-CSF (Ch. 6)
- Microsatellite repeats have a tendency to expand and can cause neuromuscular diseases such as Huntington disease and myotonic dystrophy (Ch. 7)

- L1 transposable elements can cause genetic diseases by inserting into new sites in the genome (Ch. 7)
- Exon shuffling can result in bacterial resistance to antibiotics, a growing challenge in hospitals (Ch. 7)
- Telomerase is abnormally activated in most cancers (Ch. 7)
- TFIIH subunits were first identified based on mutations in those subunits that cause defects in DNA repair associated with a stalled RNA polymerase (Ch. 8)
- HIV encodes the Tat protein, which inhibits termination of transcription by RNA polymerase II (Ch. 8)
- Synthetic oligonucleotides are being used in treatment of Duchenne muscular dystrophy (Ch. 9)
- Mutations in splicing enhancers can cause exon skipping, as in spinal muscular atrophy (Ch. 9)
- Myelodysplastic syndromes (MDS) are a group of blood cell diseases characterized by deregulated production of abnormal myelocytes (phagocytic white blood cells). Mutations in individual splicing factor genes that change protein function have been identified in MDS patients (Ch. 9)
- Thalassemia commonly results from mutations in globin-gene splice sites that decrease splicing efficiency but do not prevent association of the pre-mRNA with snRNPs (Ch. 9)
- ABO blood types are determined by the carbohydrates attached to glycoproteins on the surfaces of erythrocytes (Ch. 10)
- Atherosclerosis, marked by accumulation of cholesterol, other lipids, and other biological substances in an artery, is responsible for the majority of deaths due to cardiovascular disease in the United States (Ch. 10)

- Aquaporin 2 levels control the rate of water resorption from urine being formed by the kidney (Ch. 11)
- Certain cystic fibrosis patients are being treated with a small molecule that allows a mutant protein to traffic normally to the cell surface (Ch. 11)
- Inhibitors of the human Na^+/glucose symporter SGLT2 are in development or have been approved for treatment of type II diabetes. Antidepressants and other therapeutic drugs, as well as drugs of abuse, target Na^+-powered symporters because of their role in the reuptake and recycling of neurotransmitters (Ch. 11)
- Drugs that inhibit the Na^+/K^+ ATPase in cardiac muscle cells are used in treating congestive heart failure (Ch. 11)
- Rehydration therapy is a simple, effective means of treating cholera and other diseases caused by intestinal pathogens (Ch. 11)
- Mutations in CIC-7, a chloride ion channel, result in defective bone resorption characteristic of the hereditary bone disease osteopetrosis (Ch. 11)
- The sensitivity of mitochondrial ribosomes to the aminoglycoside class of antibiotics, including chloramphenicol, can cause toxicity in patients (Ch. 12)
- Mutations and large deletions in mtDNA cause certain diseases, such as Leber's hereditary optic neuropathy and Kearns-Sayre syndrome (Ch. 12)
- Mutations in two genes encoding the proteins PINK1 and Parkin are responsible for hereditary early onset Parkinson's disease (Ch. 12)

- Cyanide is toxic because it blocks ATP production in mitochondria (Ch. 12)
- Reactive oxygen species are by-products of electron transport that can damage cells (Ch. 12)
- ATP/ADP antiporter activity was first studied over 2000 years ago through the examination of the effects of poisonous herbs (Ch. 12)
- A hereditary form of emphysema results from misfolding of proteins in the endoplasmic reticulum (Ch. 13)
- Autosomal recessive mutations that cause defective peroxisome assembly can lead to several developmental defects often associated with craniofacial abnormalities, such as those associated with Zellweger syndrome (Ch. 13)
- Certain cases of cystic fibrosis are caused by mutations in the CFTR protein that prevent movement of this chloride channel from the ER to the cell surface (Ch. 14)
- Study of lysosomal storage diseases has revealed key elements of the lysosomal sorting pathway (Ch. 14)
- The hereditary disease familial hypercholesterolemia results from a variety of mutations in the *LDLR* gene (Ch. 14)
- EGF stimulates the proliferation of many types of epithelial cells. In about 25 percent of breast cancers, the tumor cells have elevated levels of one particular type of EGF receptor called *HER2* (Ch. 15)
- The agonist isoproterenol binds more strongly to epinephrine-responsive receptors on bronchial smooth muscle cells than does epinephrine and is used to treat bronchial asthma, chronic bronchitis, and emphysema (Ch. 15)

- Some bacterial toxins (e.g., *Bordetella pertussis*, *Vibrio cholerae*, certain strains of *E. coli*) catalyze a modification of a G protein in intestinal cells, increasing intracellular cAMP, which leads to loss of electrolytes and fluids (Ch. 15)
- In 2017, the U.S. Food and Drug Administration approved the first in vivo human gene therapy in the United States to treat blindness based on a defective RPE65 enzyme (Ch. 15)
- Monoclonal antibodies that bind HER2 and thereby block signaling by EGF are useful in treating tumors that overexpress HER2 (Ch. 16)
- Mutant Ras proteins that bind but cannot hydrolyze GTP, and are therefore locked in an active GTP-bound state, contribute to oncogenic transformation (Ch. 16)
- Potent and selective inhibitors of Raf are being clinically tested in patients with melanomas caused by mutant Raf proteins (Ch. 16)
- The deletion of the *PTEN* gene in multiple types of advanced cancers results in the loss of the PTEN protein, contributing to the uncontrolled growth of cells (Ch. 16)
- Epo and G-CSF are used to boost red blood cells in patients with kidney disease and during certain cancer therapies that affect blood cell formation in the bone marrow (Ch. 16)
- Many cases of severe combined immunodeficiency (SCID) result from a deficiency in the IL-2 receptor gamma chain and can be treated by gene therapy (Ch. 16)
- Many tumors contain inactivating mutations in either TGF-β receptors or Smad proteins and are resistant to growth inhibition by TGF-β (Ch. 16)

- High levels of free β-catenin, caused by aberrant hyperactive Wnt signaling, are associated with the activation of growth-promoting genes in many cancers (Ch. 16)
- Inappropriate activation of Hh signaling associated with primary cilia is the cause of several types of tumors (Ch. 16)
- Increased activity of ADAMs can promote cancer development and heart disease (Ch. 16)
- Hereditary spherocytic anemias can be caused by mutations in spectrin, band 4.1, and ankyrin (Ch. 17)
- Duchenne muscular dystrophy affects the protein dystrophin, resulting in progressive weakening of skeletal muscle (Ch. 17)
- Hypertrophic cardiomyopathies result from various mutations in proteins of the heart contractile machinery (Ch. 17)
- Blood tests that measure the level of cardiac-specific troponins are used to determine the severity of a heart attack (Ch. 17)
- Some drugs (e.g., colchicine) bind tubulin dimers and restrain them from polymerizing into microtubules, whereas others (e.g., taxol) bind microtubules and prevent depolymerization (Ch. 18)
- Defects in LIS1 cause Miller-Dieker lissencephaly in early brain development, leading to abnormalities (Ch. 18)
- Some diseases, such as ADPKD and Bardet-Biedl syndrome, have been traced to defects in primary cilia and intraflagellar transport (Ch. 18)
- Keratin filaments are important to maintaining the structural integrity of epithelial tissues by mechanically reinforcing the connections between cells (Ch. 18)

- Mutations in the human gene for lamin A cause a wide variety of diseases termed *laminopathies* (Ch. 18)
- In cohesinopathies, mutations in cohesion subunits or cohesion loading factors disrupt expression of genes critical for development, resulting in limb and craniofacial abnormalities and intellectual disabilities (Ch. 19)
- Mutations in the DNA repair protein BRCA1 underlie familial breast cancer (Ch. 19)
- Aneuploidy leads to misregulation of genes and can contribute to cancer development. Aneuploid eggs are largely caused by chromosome mis-segregation in meiosis I or nondisjunction, leading to miscarriage or Down syndrome (Ch. 19)
- The protein CDHR3 enables class C rhinoviruses (RV-C) to bind to airway epithelial cells, enter them, and replicate, causing respiratory diseases and exacerbating asthma (Ch. 20)
- The cadherin desmoglein is the predominant target of auto-antibodies in the skin disease pemiphigus vulgaris (Ch. 20)
- Some pathogens, such as hepatitis C virus and the enteric bacterium *Vibrio cholerae*, have evolved to exploit the molecules in tight junctions (Ch. 20)
- Mutations in connexin genes cause a variety of diseases (Ch. 20)
- Defects in the glomerular basement membrane can lead to renal failure (Ch. 20)
- In cells deprived of ascorbate, the pro-α collagen chains are not hydroxylated sufficiently to form the structural support of collagen necessary for healthy blood vessels, tendons, and skin, resulting in scurvy (Ch. 20)

- Mutations affecting type I collagen and its associated proteins cause a variety of diseases, including osteogenesis imperfecta (Ch. 20)
- A variety of diseases, often involving skeletal and cardiovascular abnormalities (e.g., Marfan syndrome), result from mutations in the genes encoding the structural proteins of elastic fibers or the proteins that contribute to their proper assembly (Ch. 20)
- Connections between the extracellular matrix and cytoskeleton are defective in muscular dystrophy (Ch. 20)
- Leukocyte-adhesion deficiency is caused by a genetic defect that results in the leukocytes' inability to fight infection, thereby increasing susceptibility to repeated bacterial infections (Ch. 20)
- Diabetes mellitus is characterized by impaired regulation of blood glucose, which can lead to major complications if left untreated (Ch. 21)
- Genes encoding components of the mTORC1 pathway are mutated in many cancers, and mTor inhibitors combined with other therapies may suppress tumor growth (Ch. 21)
- In kidney tumors with a mutation in the von Hippel-Landau (VHL) gene, the loss of VHL protein activity leads to an increase in the expression of Hif-1α target genes, including VEGF (Ch. 21)
- The importance of circadian rhythms ranges from the use of cells in tissue culture to disorders such as Alzheimer's disease and autism spectrum disorder (Ch. 21)
- Because iPS cells can be derived from somatic cells of patients with difficult-to-understand diseases, they have proved

invaluable in uncovering the molecular and cellular basis of several afflictions, including amyotrophic lateral sclerosis (ALS) (Ch. 22)

- The stem cells in transplanted bone marrow can generate all types of functional blood cells, which makes such transplants useful for patients with certain hereditary blood diseases as well as cancer patients who have received irradiation or chemotherapy (Ch. 22)
- Channelopathies, including some forms of epilepsy, are caused by mutations in genes that encode ion channels (Ch. 23)
- The topical anesthetic lidocaine works by binding to amino acid residues along the voltage-gated Na^+ channel, locking it in the open but occluded state (Ch. 23)
- The cause of multiple sclerosis is not known, but seems to involve either the body's production of auto-antibodies that react with myelin basic protein or the secretion of proteases that destroy myelin proteins (Ch. 23)
- Peripheral myelin is a target of autoimmune disease, mainly involving the formation of antibodies against P_0 (Ch. 23)
- The key role of VAMP in neurotransmitter exocytosis can be seen in the mechanism of action of botulinum toxin (Ch. 23)
- Neurotransmitter transporters are targets of a variety of drugs of abuse (e.g., cocaine) as well as therapeutic drugs commonly used in psychiatry (e.g., Prozac, Zoloft, Paxil) (Ch. 23)
- Nicotinic acetylcholine receptors produced in brain neurons are important in learning and memory; loss of these receptors is observed in schizophrenia, epilepsy, drug addiction, and Alzheimer's disease (Ch. 23)

- People vary significantly in their ability to detect certain odors (Ch. 23)
- Synaptic translation of localized mRNAs is critical to the formation and the experience-dependent plasticity of neural circuits; alterations in this process result in neurodevelopmental and cognitive disorders (Ch. 23)
- People with defects in RAG gene function have no B cells and suffer from severe immunodeficiency (Ch. 24)
- The immunosuppressant drug cyclosporine inhibits calcineurin activity through the formation of a cyclosporine-cyclophilin complex, thus enabling successful allogenic tissue transplantation (Ch. 24)
- Vaccines elicit protective immunity against a variety of pathogens (Ch. 24)
- The immune system may also help in warding off cancer (Ch. 24)
- Increased understanding of the molecular cell biology of tumors is revolutionizing the way cancers are diagnosed and treated (Ch. 25)
- Using the loss of DNA repair in tumors for targeted chemotherapy (Ch. 25)
- Breast cancer as an example of how molecular cell biology techniques have affected both curative and palliative cancer treatment (Ch. 25)

Plant Biology Connections

Developments in agriculture, environmental science, and alternative energy production have demonstrated that the molecular cell biology of plants is increasingly relevant to our lives. Understanding photosynthesis and chloroplasts is just the beginning of plant biology. Throughout the text, we have highlighted plant-specific topics, including aspects of cell structure and function that are unique to plants, plant development, and plant biotechnology applications directed toward solving problems in agriculture and medicine.

- Vascular plants have rigid cell walls and use turgor pressure to stand upright and grow (Ch. 11)
- Transgenic plants have been produced that overexpress the vacuolar Na^+/H^+ antiporter, and can therefore grow successfully in soils containing high salt concentrations (Ch. 11)
- Chloroplast transformation has led to engineered plants that are resistant to infections as well as plants that can be used to make protein drugs (Ch. 12)
- In giant green algae such as *Nitella*, the cytosol flows rapidly due to use of myosin V (Ch. 17)
- Formation of the spindle and cytokinesis have unique features in plants (Ch. 18)
- The Venus flytrap is a well-known example of macroscopic plant mechanosensation (Ch. 20)
- Expression of a group of cell-wall degrading enzymes and their remodeling of cell walls by degrading pectin plays a key role in determining the rate and extent of the softening of fruit (Ch. 20)
- Meristems are niches for stem cells in plants (Ch. 22)

- A negative feedback loop maintains the size of the shoot apical stem-cell population (Ch. 22)
- The root meristem resembles the shoot meristem in structure and function (Ch. 22)

Acknowledgments

This edition would not have been possible without the careful and committed collaboration of our publishing partners at Macmillan Learning. We thank Daryl Fox, Sandy Lindelof, Lisa Lockwood, Will Moore, Debbie Hardin, Katrina Mangold, Karen S. Misler, Nathan Livingston, Tracey Kuehn, Jennifer MacMillan, Krystyna Borgen, Cassandra Korsvik, Lisa Kinne, Peter Jacoby, Diana Blume, Paul Rohloff, Natasha Wolfe, John Callahan, Matt McAdams, Keri deManigold, and Daniel Comstock for their labor and for their willingness to work overtime to produce a book that excels in every way.

In particular, we would like to acknowledge the talent and commitment of our text editors, Michael Zierler, Maria Lokshin, and Anna Bristow. They are remarkable editors. Thank you for all you've done in this edition.

We are also indebted to H. Adam Steinberg for his pedagogical insight and his development of beautiful molecular models and illustrations.

We would like to acknowledge those whose direct contributions to previous editions continue to influence in this edition, especially Ruth Steyn.

Thanks to our own staff: Sally Bittancourt, Diane Bush, Mary Anne Donovan, Carol Eng, James Evans, Julie Knight, George Kokkinogenis, Guicky Waller, Nicki Watson, and Rob Welsh.

Special thanks to our families for inspiring us and for granting us the time it takes to work on such a book and to our mentors and advisers for encouraging us in our studies and teaching us much of what we know: *(Harvey Lodish)* my wife, Pamela; my children and grandchildren Heidi and Eric Steinert and Emma and Andrew Steinert; Martin Lodish, Kristin Schardt, and Sophia, Joshua, and Tobias Lodish; and Stephanie Lodish, Bruce Peabody, and Isaac and Violet Peabody; mentors Norton Zinder and Sydney Brenner; and also David Baltimore and Jim Darnell for collaborating on the first editions of this book; *(Arnold Berk)* my wife, Sally, Jerry Berk, Shirley Berk, Angelina Smith, David Clayton, and Phil Sharp; *(Chris A. Kaiser)* my wife, Kathy O'Neill, my mentors David Botstein and Randy Schekman; *(Monty Krieger)* my wife, Nancy Krieger, parents I. Jay Krieger and Mildred Krieger, children Joshua and Ilana Krieger and Jonathan Krieger and Sofia Colucci, and grandchildren Joaquin, Alejandro, and Ari Krieger; my mentors Robert Stroud, Michael Brown, and Joseph Goldstein; *(Anthony Bretscher)* my wife, Janice, and daughters Heidi and Erika, and advisers A. Dale Kaiser and Klaus Weber; *(Kelsey C. Martin)* my husband, Joel Braslow, children Seth, Ben, Sam, and Maya, father George M. Martin, and mentors Ari Helenius and Eric Kandel; *(Michael B. Yaffe)* my wife Sung-Yun Pai and sons Samkyu and Minkyu, and my mentors Himan

Sternlicht and Lewis Cantley; *(Angelika Amon)* my husband, Johannes Weis, Theresa and Clara Weis, Gerry Fink and Frank Solomon.

Finally, in updating, revising, and rewriting this book, we were given invaluable help by many colleagues. We thank the following people who generously gave of their time and expertise by making contributions to specific chapters in their areas of interest, providing us with detailed information about their courses, or by reading and commenting on one or more chapters.

Contents

Preface

Part I Chemical and Molecular Foundations

1 Evolution: Molecules, Genes, Cells, and Organisms

1.1 The Molecules of Life

- Proteins Give Cells Structure and Perform Most Cellular Tasks
- Nucleic Acids Carry Coded Information for Making Proteins at the Right Time and Place
- Phospholipids Are the Conserved Building Blocks of All Cellular Membranes
- Quality Control of All Cellular Macromolecules Is Essential for Life

1.2 Prokaryotic Cell Structure and Function

- Prokaryotes Comprise Two Kingdoms: Archaea and Eubacteria
- Many Bacteria Including *Escherichia coli* Are Widely Used in Biological Research

1.3 Eukaryotic Cell Structure and Function

- The Cytoskeleton Has Many Important Functions
- The Nucleus Contains the DNA Genome, Apparatuses for Synthesis of DNA and RNA, and a Fibrous Matrix

The Endoplasmic Reticulum Is the Site of Synthesis of Most Membrane and Secreted Proteins as Well as Many Lipids

The Golgi Complex Sorts Secreted Proteins and Many Membrane Proteins to Their Final Destinations in the Cell

Endosomes Bring Proteins and Particles from the Outside into Cells

Lysosomes Are Cellular Recycling Centers

Plant Vacuoles Store Water, Ions, and Small-Molecule Nutrients Such as Sugars and Amino Acids

Peroxisomes and Plant Glyoxisomes Metabolize Fatty Acids and Other Small Molecules Without Producing ATP from ADP and P_i

Mitochondria Are the Principal Sites of ATP Production in Aerobic Cells

Chloroplasts Contain Internal Compartments in Which Photosynthesis Takes Place

Many Organelle-Like Structures Are Unbounded by a Membrane

All Eukaryotic Cells Use a Similar Cycle to Regulate Their Division

1.4 Unicellular Eukaryotic Organisms Widely Used in Cell Biology Research

Yeasts Are Used to Study Fundamental Aspects of Eukaryotic Cell Structure and Function

Mutations in Yeast Led to the Identification of Key Cell Cycle Proteins

Studies in the Alga *Chlamydomonas reinhardtii* Led to the Development of a Powerful Technique to Study Brain Function

The Parasite That Causes Malaria Has Novel Organelles That Allow It to Undergo a Remarkable Life Cycle

1.5 Metazoan Structure, Function, Evolution, and Differentiation

Multicellularity Requires Cell-Cell and Cell-Matrix Adhesions

Epithelia Originated Early in Evolution

Cells Are Organized into Tissues and Tissues into Organs

Genomics Has Revealed Important Aspects of Metazoan Evolution and Cell Function

Development Uses a Conserved Set of Master Transcription Factors and Involves Epigenetic Modifications to DNA and Its Associated Histone Proteins

1.6 Metazoan Organisms Widely Used in Cell Biology Research

Drosophila melanogaster and *Caenorhabditis elegans* Are Used to Identify Genes That Regulate Animal Development

Planaria Are Used to Study Stem Cells and Tissue Regeneration

Studies on Fish, Mice, and Other Vertebrate Organisms Inform the Study of Human Development and Disease

Human Genetic Diseases Elucidate Important Aspects of Cell Function

Unbiased Single Cell Sequencing Experiments Identify Altogether New Cell Types

The Following Chapters Present Many Experimental Techniques and Much Experimental Data That Explains How We Know What We Know About Cell Structure and Function

2 Chemical Foundations

2.1 Covalent Bonds and Noncovalent Interactions

The Electronic Structure of an Atom Determines the Number and Geometry of the Covalent Bonds It Can Make

All Covalent Bonds Are Not Equal: Electrons May Be Shared Equally or Unequally in Covalent Bonds

Covalent Bonds Are Much Stronger and More Stable Than Noncovalent Interactions

Ionic Bonds Are Noncovalent Interactions Formed by the Electrostatic Attractions Between Oppositely Charged Ions

Hydrogen Bonds Are Noncovalent Interactions That Determine the Properties of Water and the Water Solubility of Uncharged Molecules

Van der Waals Interactions Are Weak Attractive Interactions Caused by Transient Dipoles

The Hydrophobic Effect Causes Nonpolar Molecules to Adhere to One Another

Molecular Complementarity Due to Noncovalent Interactions Leads to a Lock-and-Key Fit Between Biomolecules

2.2 Chemical Building Blocks of Cells

Amino Acids Differing Only in Their Side Chains Compose Proteins

Five Different Nucleotides Are Used to Build Nucleic Acids

Monosaccharides Covalently Assemble into Linear and Branched Polysaccharides

Phospholipids Associate Noncovalently to Form the Basic Bilayer Structure of Biomembranes

2.3 Chemical Reactions and Chemical Equilibrium

A Chemical Reaction Is in Equilibrium When the Rates of the Forward and Reverse Reactions Are Equal

The Equilibrium Constant Reflects the Extent of a Chemical Reaction

Chemical Reactions in Cells Are at Steady State

Dissociation Constants of Binding Reactions Reflect the Affinity of Interacting Molecules

Biological Fluids Have Characteristic pH Values

Hydrogen Ions Are Released by Acids and Taken Up by Bases

Buffers Maintain the pH of Intracellular and Extracellular Fluids

2.4 Biochemical Energetics

Several Forms of Energy Are Important in Biological Systems

Cells Can Transform One Type of Energy into Another

The Change in Free Energy Determines If a Chemical Reaction Will Occur Spontaneously

The $\Delta G^{\circ\prime}$ of a Reaction Can Be Calculated from Its K_{eq}

The Rate of a Reaction Depends on the Activation Energy Necessary to Energize the Reactants into a Transition State

Life Depends on the Coupling of Energetically Unfavorable Chemical Reactions with Energetically Favorable Ones

Hydrolysis of ATP Releases Substantial Free Energy and Drives Many Cellular Processes

ATP Is Generated During Photosynthesis and Respiration

NAD^+ and FAD Couple Many Biological Oxidation and Reduction Reactions

3 Protein Structure and Function

3.1 Hierarchical Structure of Proteins

The Primary Structure of a Protein Is Its Linear Arrangement of Amino Acids

Secondary Structures Are the Core Elements of Protein Architecture

Structural Motifs Are Regular Combinations of Secondary Structures

Tertiary Structure Is the Overall Folding of a Polypeptide Chain

Different Ways of Depicting the Conformation of Proteins Convey Different Types of Information

Domains Are Modules of Tertiary Structure

Comparing Protein Sequences and Structures Provides Insight into Protein Function and Evolution

There Are Four Broad Structural Categories of Proteins

Multiple Polypeptides Assemble into Quaternary Structures, Supramolecular Complexes, and Biomolecular Condensates

3.2 Protein Folding

Planar Peptide Bonds Limit the Shapes into Which Proteins Can Fold

Protein Folding Is Promoted by Proline Isomerases

The Amino Acid Sequence of a Protein Determines How It Will Fold

Folding of Proteins In Vivo Is Promoted by Chaperones

Abnormally Folded Proteins Can Form Amyloids That Are Implicated in Diseases

3.3 Protein Binding and Enzyme Catalysis

Specific Binding of Ligands Underlies the Functions of Most Proteins

Enzymes Are Highly Efficient and Specific Catalysts

An Enzyme's Active Site Binds Substrates and Carries Out Catalysis

Serine Proteases Demonstrate How an Enzyme's Active Site Works

Enzymes in a Common Pathway Are Often Physically Associated with One Another

3.4 Regulating Protein Function

Regulated Synthesis and Degradation of Proteins Is a Fundamental Property of Cells

The Proteasome Is a Molecular Machine Used to Degrade Proteins

Ubiquitin Marks Cytosolic Proteins for Degradation in Proteasomes

Noncovalent Binding Permits Allosteric, or Cooperative, Regulation of Proteins

Noncovalent Binding of Calcium and GTP Are Widely Used as Allosteric Switches to Control Protein Activity

Covalent Modification of Proteins Can Regulate their Activities

Phosphorylation and Dephosphorylation Covalently Regulate Protein Activity

The Structure and Function of Protein Kinase A Is Typical of Many Kinases

Protein Kinase Activity Is Often Regulated by Phosphorylation of the Kinase

Ubiquitinylation and Deubiquitinylation Covalently Regulate Protein Activity

Proteolytic Cleavage Irreversibly Activates or Inactivates Some Proteins

Higher Order Regulation Includes Control of Protein Location

3.5 Purifying, Detecting, and Characterizing Proteins

Centrifugation Can Separate Particles and Molecules That Differ in Mass or Density

Electrophoresis Separates Molecules on the Basis of Their Charge-to-Mass Ratio

Liquid Chromatography Resolves Proteins by Mass, Charge, or Affinity

Highly Specific Enzyme and Antibody Assays Can Detect Individual Proteins

Radioisotopes Are Indispensable Tools for Detecting Biological Molecules

Mass Spectrometry Can Determine the Mass and Sequence of Proteins

Protein Primary Structure Can Be Determined by Chemical Methods and from Gene Sequences

Protein Conformation Is Determined by Sophisticated Physical Methods

3.6 Proteomics

Proteomics Is the Study of All or a Large Subset of Proteins in a Biological System

Advanced Techniques in Mass Spectrometry Are Critical to Proteomic Analysis

4 Culturing and Visualizing Cells

4.1 Growing and Studying Cells in Culture

Culture of Animal Cells Requires Nutrient-Rich Media and Special Solid Surfaces

Primary Cell Cultures and Cell Strains Have a Finite Life Span

Transformed Cells Can Grow Indefinitely in Culture

Flow Cytometry Separates Different Cell Types

Growth of Cells in Two-Dimensional and Three-Dimensional Culture Mimics the In Vivo Environment

Stem Cells Can Differentiate in Culture to Make Organoids

Hybridomas Produce Abundant Monoclonal Antibodies

A Wide Variety of Cell Biological Processes Can Be Studied with Cultured Cells

Drugs Are Commonly Used in Cell Biological Research

4.2 Light Microscopy: Exploring Cell Structure and Visualizing Proteins Within Cells

The Resolution of the Conventional Light Microscope Is About 0.2 μm

Phase-Contrast and Differential-Interference-Contrast Microscopy Visualize Unstained Live Cells

Imaging Subcellular Details Often Requires That Specimens Be Fixed, Sectioned, and Stained

Fluorescence Microscopy Can Localize and Quantify Specific Molecules in Live Cells

Intracellular Ion Concentrations Can Be Determined with Ion-Sensitive Fluorescent Dyes

Immunofluorescence Microscopy Can Detect Specific Proteins in Fixed Cells

Tagging with Fluorescent Proteins Allows the Visualization of Specific Proteins in Live Cells

Deconvolution and Confocal Microscopy Enhance Visualization of Three-Dimensional Fluorescent Objects

Two-Photon Excitation Microscopy Allows Imaging Deep into Tissue Samples

TIRF Microscopy Provides Exceptional Imaging in One Focal Plane

FRAP Reveals the Dynamics of Cellular Components

FRET Measures Distance Between Fluorochromes

Optogenetics Allows Light to Regulate Events in a Spatial and Temporal Manner

Point Source Fluorescent Objects Can Be Located at Nanometer Resolution

Super-Resolution Microscopy Can Localize Proteins to Nanometer Accuracy

Light-Sheet Microscopy Can Rapidly Image Cells in Living Tissue

4.3 Electron Microscopy: High-Resolution Imaging

Single Molecules or Structures Can Be Imaged Using a Negative Stain or Metal Shadowing

Cells and Tissues Are Cut into Thin Sections for Viewing by Electron Microscopy

Immunoelectron Microscopy Localizes Proteins at the Ultrastructural Level

Cryoelectron Microscopy Allows Visualization of Specimens Without Fixation or Staining

Scanning Electron Microscopy of Metal-Coated Specimens Reveals Surface Features

4.4 Isolation of Cell Organelles

Disruption of Cells Releases Their Organelles and Other Contents

Centrifugation Can Separate Many Types of Organelles

Organelle-Specific Antibodies Are Useful in Preparing Highly Purified Organelles

Proteomics Reveals the Protein Composition of Organelles

Part II Biomembranes, Genes, and Gene Regulation

5 Fundamental Molecular Genetic Mechanisms

5.1 The Double-Helical Structure of DNA

Native DNA Is a Double Helix of Complementary Antiparallel Strands

DNA Can Undergo Reversible Strand Separation

DNA Molecules Can Acquire Torsional Stress

5.2 DNA Replication

DNA Polymerases Require a Template and a Primer to Replicate DNA

Duplex DNA Is Unwound, and Daughter Strands Are Formed at the DNA Replication Fork

A DNA Replication Fork Advances by Cooperation of Multiple Proteins

DNA Replication Occurs Bidirectionally from Each Origin

5.3 DNA Repair and Recombination

Chemical and Radiation Damage to DNA Can Lead to Mutations

High-Fidelity DNA Excision-Repair Systems Recognize and Repair Damage

Base Excision Repairs T-G Mismatches and Damaged Bases

Mismatch Excision Repairs Other Mismatches and Small Insertions and Deletions

Nucleotide Excision Repairs Chemical Adducts That Distort Normal DNA Shape

Two Systems Use Recombination to Repair Double-Strand Breaks in DNA

Homologous Recombination Can Repair DNA Damage and Generate Genetic Diversity

5.4 Transcription of Protein-Coding Genes and Formation of mRNA

A Template DNA Strand Is Transcribed into a Complementary RNA Strand by RNA Polymerase

Eukaryotic Precursor mRNAs Are Processed to Form Functional mRNAs

Alternative RNA Splicing Increases the Number of Proteins That Can Be Expressed from a Single Eukaryotic Gene

5.5 The Decoding of mRNA by tRNAs

Messenger RNA Carries Information from DNA in a Three-Letter Genetic Code

The Folded Structure of tRNA Promotes Its Decoding Functions

Nonstandard Base Pairing Often Occurs Between Codons and Anticodons

Amino Acids Are Linked to Their Cognate tRNAs with Great Accuracy

5.6 Stepwise Synthesis of Proteins on Ribosomes

Ribosomes Are Protein-Synthesizing Machines

Methionyl-$tRNA_i^{Met}$ Recognizes the AUG Start Codon

Eukaryotic Translation Initiation Usually Occurs at the First AUG Downstream from the 5′ End of an mRNA

During Chain Elongation Each Incoming Aminoacyl-tRNA Moves Through Three Ribosomal Sites

Translation Is Terminated by Release Factors When a Stop Codon Is Reached

Polysomes and Rapid Ribosome Recycling Increase the Efficiency of Translation

GTPase-Superfamily Proteins Function in Several Quality-Control Steps of Translation

Nonsense Mutations Can Be Bypassed by Suppressing tRNA Mutations

5.7 Viruses: Parasites of the Cellular Genetic System

Most Viral Host Ranges Are Narrow

Viral Capsids Are Regular Arrays of One or a Few Types of Protein

Lytic Viral Growth Cycles Lead to Death of Host Cells

Viral DNA Is Integrated into the Host-Cell Genome in Some Nonlytic Viral Growth Cycles

6 Molecular Genetic Techniques

6.1 Using Genetic Analysis of Mutations to Identify and Study Genes

Recessive and Dominant Mutant Alleles Generally Have Opposite Effects on Gene Function

Segregation of Mutations in Breeding Experiments Reveals Whether They Are Dominant or Recessive

Conditional Mutations Can Be Used to Study Essential Genes in Yeast

Recessive Lethal Mutations in Diploids Can Be Identified by Inbreeding and Maintained in Heterozygotes

Complementation Tests Determine Whether Different Recessive Mutations Are in the Same Gene

Double Mutants Are Useful in Assessing the Order in Which Proteins Function

Genetic Suppression and Synthetic Lethality Can Reveal Interacting or Redundant Proteins

Global Analysis of Double Mutant Combinations Can Reveal Networks of Gene Functions

6.2 DNA Cloning and Characterization

Restriction Enzymes and DNA Ligases Allow Insertion of DNA Fragments into Cloning Vectors

Isolated DNA Fragments Can Be Cloned into *E. coli* Plasmid Vectors

Yeast Genomic Libraries Can Be Constructed with Shuttle Vectors and Screened by Functional Complementation

cDNA Libraries Represent the Sequences of Protein-Coding Genes

The Polymerase Chain Reaction Amplifies a Specific DNA Sequence from a Complex Mixture

Cloned DNA Molecules Can Be Sequenced Rapidly by Methods Based on PCR

6.3 Using Sequence Information to Identify Genes and Deduce Their Function

Most Genes Can Be Readily Identified Within Genomic DNA Sequences

Bioinformatic Principles Can Be Used to Deduce the Likely Functional Consequences of Mutations

The Function and Evolutionary Origins of Genes and Proteins Can Be Deduced from Their Sequence

Comparison of Related Sequences from Different Species Can Give Clues to Evolutionary Relationships Among Proteins

Biological Complexity of an Organism Is Not Directly Related to the Number of Protein-Coding Genes in the Genome

6.4 Locating and Identifying Genes That Specify Human Traits

Monogenic Diseases Show One of Three Patterns of Inheritance

DNA Polymorphisms Are Used as Markers for Linkage Mapping of Human Mutations

Human Linkage Studies Can Map Disease Genes with a Resolution of About 1 Mbp

Further Analysis Is Needed to Locate a Disease Gene in Cloned DNA

Most Inherited Diseases Result from Multiple Genetic Defects

Identifying Component Genetic Risk Factors of Complex Traits

Medically Important Genes Can Be Identified by Alleles That Protect Against Disease

Identification of Causative Mutations in Cancer Cells

6.5 Using Cloned DNA Fragments to Study Gene Expression

In Situ Hybridization Techniques Permit Detection of Specific mRNAs

DNA Microarrays Can Be Used to Evaluate the Expression of Many Genes at Once

Cluster Analysis of Multiple Expression Experiments Identifies Co-Regulated Genes

Sequencing of cDNAs Allows Analysis of Gene Expression in Individual Cells

E. coli Expression Systems Can Produce Large Quantities of Proteins from Cloned Genes

Plasmid Expression Vectors Can Be Designed for Use in Animal Cells

6.6 Altering the Function of Specific Genes by Design

Normal Yeast Genes Can Be Replaced with Mutant Alleles by Homologous Recombination

Engineered CRISPR Systems Allow Precise Genome Editing

Somatic Cell Recombination Can Inactivate Genes in Specific Tissues of Mice

RNA Interference Causes Gene Inactivation by Destroying the Corresponding mRNA

7 Genes, Chromatin, and Chromosomes

7.1 Eukaryotic Gene Structure and Organization

Most Genes of Multicellular Eukaryotes Contain Introns and Produce mRNAs Encoding Single Proteins

Simple and Complex Transcription Units Are Found in Eukaryotic Genomes

Protein-Coding Genes May Be Solitary or Belong to a Gene Family

Heavily Used Gene Products Are Encoded by Multiple Copies of Genes

Nonprotein-Coding Genes Encode Functional RNAs

7.2 Chromosomal Organization of Genes and Noncoding DNA

Genomes of Many Organisms Contain a Large Fraction of Noncoding DNA

Most Simple-Sequence DNAs Are Concentrated in Specific Chromosomal Locations

DNA Fingerprinting Depends on Differences in Length of Simple-Sequence DNAs

Unclassified Intergenic DNA Occupies a Significant Portion of the Genome

7.3 Transposable (Mobile) DNA Elements

Movement of Mobile Elements Involves a DNA or an RNA Intermediate

Most Mobile Elements in Bacteria Are DNA Transposons Known as Insertion Sequences

Eukaryotic DNA Transposons Move Using a Cut-and-Paste Process

LTR Retrotransposons Behave Like Intracellular Retroviruses

Non-LTR Retrotransposons Transpose by a Distinct Mechanism

Other Retroposed RNAs Are Found in Genomic DNA

Mobile DNA Elements Have Significantly Influenced Evolution

7.4 Structural Organization of Eukaryotic Chromatin and Chromosomes

Chromatin Is Made of Nucleosomes

Chromatin Structure Is Conserved Among Eukaryotes

Chromatin Is a Disordered Chain of Nucleosomes Packed Together at Different Concentration Densities in the Nucleus

Modifications of Histone Tails Control Chromatin Condensation and Function

Additional Nonhistone Proteins Regulate Transcription and Replication

7.5 Morphology and Functional Elements of Eukaryotic Chromosomes

Chromosome Number, Size, and Shape at Metaphase Are Species-Specific

During Metaphase, Chromosomes Can Be Distinguished by Banding Patterns and Chromosome Painting

Chromosome Painting and DNA Sequencing Reveal the Evolution of Chromosomes

Interphase Polytene Chromosomes Arise by DNA Amplification

Three Functional Elements Are Required for Replication and Stable Inheritance of Chromosomes

Centromere Sequences Vary Greatly in Length and Complexity

Addition of Telomeric Sequences by Telomerase Prevents Shortening of Chromosomes

8 Transcriptional Control of Gene Expression

8.1 Overview of Eukaryotic Transcription

Regulatory Elements in Eukaryotic DNA Are Found Both Close to and Many Kilobases Away from Transcription Start Sites

Three Eukaryotic Nuclear RNA Polymerases Catalyze Formation of Different RNAs

The Clamp Domain Enables RNA Polymerase II to Transcribe Long Stretches of DNA

The Largest Subunit in RNA Polymerase II Has an Essential Carboxy-Terminal Repeat

8.2 RNA Polymerase II Promoters and General Transcription Factors

RNA Polymerase II Initiates Transcription at DNA Sequences Corresponding to the 5′ Cap of mRNAs

The TATA Box, Initiators, and CpG Islands Function as Promoters in Eukaryotic DNA

General Transcription Factors Position RNA Polymerase II at Transcription Start Sites and Assist in Initiation

Elongation Factors Regulate the Initial Stages of Transcription in the Promoter-Proximal Region

8.3 Regulatory Sequences for Protein-Coding Genes and the Proteins Through Which They Function

Promoter-Proximal Elements Help Regulate Eukaryotic Genes

Distant Enhancers Often Stimulate Transcription by RNA Polymerase II

Most Eukaryotic Genes Are Regulated by Multiple Transcription-Control Elements

DNase I Footprinting and EMSA Detect Protein-DNA Interactions

Activators Are Composed of Distinct Functional Domains

Repressors Are the Functional Converse of Activators

DNA-Binding Domains Can Be Classified into Numerous Structural Types

Structurally Diverse Activation and Repression Domains Regulate Transcription

Transcription Factor Interactions Increase Gene-Control Options

Multiprotein Complexes Form on Enhancers

8.4 Molecular Mechanisms of Transcription Repression and Activation

Formation of Heterochromatin Silences Gene Expression at Telomeres, near Centromeres, and in Other Regions

Repressors Can Direct Histone Deacetylation at Specific Genes

Activators Can Direct Histone Acetylation at Specific Genes

Chromatin-Remodeling Complexes Help Activate or Repress Transcription

Pioneer Transcription Factors Initiate the Process of Gene Activation During Cellular Differentiation

The Mediator Complex Forms a Molecular Bridge Between Activation Domains and Pol II

Transcriptional Condensates Greatly Increase the Rate of Transcription Initiation

Transcription Occurs in Bursts

8.5 Regulation of Transcription-Factor Activity

DNase I Hypersensitive Sites Reflect the Developmental History of Cellular Differentiation

Nuclear Receptors Are Regulated by Lipid-Soluble Hormones

All Nuclear Receptors Share a Common Domain Structure

Nuclear-Receptor Response Elements Contain Inverted or Direct Repeats

Hormone Binding to a Nuclear Receptor Regulates Its Activity as a Transcription Factor

Metazoans Regulate the RNA Polymerase II Transition from Initiation to Elongation

Termination of Transcription Is Also Regulated

8.6 Epigenetic Regulation of Transcription

DNA Methylation Regulates Transcription

Methylation of Specific Histone Lysines Is Linked to Epigenetic Mechanisms of Gene Repression

Epigenetic Control by Polycomb and Trithorax Complexes

Long Noncoding RNAs Direct Epigenetic Repression in Metazoans

8.7 Other Eukaryotic Transcription Systems

Transcription Initiation by Pol I and Pol III Is Analogous to That by Pol II

9 Post-Transcriptional Gene Control

9.1 Processing of Eukaryotic Pre-mRNA

The 5′ Cap Is Added to Nascent RNAs Shortly After Transcription Initiation

Chain Elongation by RNA Polymerase II Is Coupled to the Presence of RNA Processing Factors

A Diverse Set of Proteins with Conserved RNA-Binding Domains Associate with Pre-mRNAs

Splicing Occurs at Short, Conserved Sequences in Pre-mRNAs via Two Transesterification Reactions

During Splicing, snRNAs Base-Pair with Pre-mRNA to Select Splice Sites and Guide the Transesterification Reactions

Spliceosomes Catalyze Pre-mRNA Splicing

3′ Cleavage and Polyadenylation of Pre-mRNAs Are Tightly Coupled

9.2 Regulation of Pre-mRNA Processing

Additional Nuclear Proteins Contribute to Splice-Site Selection in the Long Pre-mRNAs of Humans and Other Vertebrates

Expression and Function of Related K^+-Channel Protein Isoforms in Vertebrate Inner Ear Hair Cells

Regulation of RNA Splicing Through Splicing Enhancers and Silencers Controls *Drosophila* Sexual Differentiation

Splicing Repressors and Activators Control Splicing at Alternative Sites

Expression of *Dscam* Isoforms in *Drosophila* Retinal Neurons

Abnormal RNA Splicing and Disease

Self-Splicing Group II Introns Provide Clues to the Evolution of snRNAs

Nuclear Exonucleases and the Exosome Degrade RNA That Is Processed out of Pre-mRNAs

RNA Processing Solves the Problem of Pervasive Transcription of the Genome in Mammalian Cells

RNA Editing Alters the Sequences of Some Pre-mRNAs

9.3 Transport of mRNA Across the Nuclear Envelope

SR Proteins Mediate Nuclear Export of mRNA

Pre-mRNAs Associated with Spliceosomes Are Not Exported from the Nucleus

HIV Rev Protein Regulates the Transport of Unspliced Viral mRNAs

9.4 Cytoplasmic Mechanisms of Post-Transcriptional Control

The Concentration of an mRNA in the Cytoplasm Is Determined by Its Rate of Synthesis and Its Rate of Degradation

Degradation of mRNAs in the Cytoplasm Occurs by Several Mechanisms

MicroRNAs Repress Translation and Induce Degradation of Specific mRNAs

RNA Interference Induces Degradation of Precisely Complementary mRNAs

Cytoplasmic Polyadenylation Promotes Translation of Some mRNAs

Protein Synthesis Can Be Globally Regulated

Sequence-Specific RNA-Binding Proteins Control Specific mRNA Translation

Surveillance Mechanisms Prevent Translation of Improperly Processed mRNAs

Localization of mRNAs Permits Production of Proteins at Specific Regions Within the Cytoplasm

9.5 Processing of rRNA and tRNA

Pre-rRNA Genes Are Similar in All Eukaryotes and Function as Nucleolar Organizers

Small Nucleolar RNAs Assist in Processing Pre-rRNAs

Self-Splicing Group I Introns Were the First Examples of Catalytic RNA

Pre-tRNAs Undergo Extensive Modification in the Nucleus

9.6 Nuclear Bodies Are Functionally Specialized Nuclear Domains

Cajal Bodies

Nuclear Speckles

Nuclear Paraspeckles

Promyelocytic Leukemia (PML) Nuclear Bodies

Nucleolar Functions in Addition to Ribosomal Subunit Synthesis

10 Biomembrane Structure

10.1 The Lipid Bilayer: Composition and Structural Organization

Phospholipids Spontaneously Form Bilayers

Phospholipid Bilayers Form a Sealed Compartment Surrounding an Internal Aqueous Space

Biomembranes Contain Three Principal Classes of Lipids

Most Lipids and Many Proteins Are Laterally Mobile in Biomembranes

Lipid Composition Influences the Physical Properties of Membranes

Lipid Composition Is Different in the Exoplasmic and Cytosolic Leaflets

Cholesterol and Sphingolipids Cluster with Specific Proteins in Membrane Microdomains

Cells Store Excess Lipids in Lipid Droplets

10.2 Membrane Proteins: Structure and Basic Functions

Proteins Interact with Membranes in Three Different Ways

Most Transmembrane Proteins Have Membrane-Spanning α Helices

Multiple β Strands in Porins Form Membrane-Spanning "Barrels"

Covalently Attached Lipids Anchor Some Proteins to Membranes

All Transmembrane Proteins and Glycolipids Are Asymmetrically Oriented in the Bilayer

Lipid-Binding Motifs Help Target Peripheral Proteins to the Membrane

Proteins Can Be Removed from Membranes by Detergents or High-Salt Solutions

10.3 Phospholipids, Sphingolipids, and Cholesterol: Synthesis and Intracellular Movement

Fatty Acids Are Assembled from Two-Carbon Building Blocks by Several Important Enzymes

Small Cytosolic Proteins Facilitate Movement of Fatty Acids

Fatty Acids Are Incorporated into Phospholipids Primarily on the ER Membrane

Flippases Move Phospholipids from One Membrane Leaflet to the Opposite Leaflet

Cholesterol Is Synthesized by Enzymes in the Cytosol and ER Membrane

Cholesterol and Phospholipids Are Transported Between Organelles by Several Mechanisms

Part III Cellular Organization and Function

11 Transmembrane Transport of Ions and Small Molecules

11.1 Overview of Transmembrane Transport

Only Gases and Small Uncharged Molecules Cross Membranes by Simple Diffusion

Three Main Classes of Membrane Proteins Transport Molecules and Ions Across Cellular Membranes

11.2 Facilitated Transport of Glucose and Water

Uniport Transport Is Faster and More Specific than Simple Diffusion

The Low K_m of the GLUT1 Uniporter Enables It to Transport Glucose into Most Mammalian Cells

The Human Genome Encodes a Family of Sugar-Transporting GLUT Proteins

Transport Proteins Can Be Studied Using Artificial Membranes and Recombinant Cells

Osmotic Pressure Causes Water to Move Across Membranes

Aquaporins Increase the Water Permeability of Cellular Membranes

11.3 ATP-Powered Pumps and the Intracellular Ionic Environment

There Are Four Main Classes of ATP-Powered Pumps

ATP-Powered Ion Pumps Generate and Maintain Ionic Gradients Across Cellular Membranes

Muscle Relaxation Depends on Ca^{2+} ATPases That Pump Ca^{2+} from the Cytosol into the Sarcoplasmic Reticulum

The Mechanism of Action of the Ca^{2+} Pump Is Known in Detail

The Na^+/K^+ ATPase Maintains the Intracellular Na^+ and K^+ Concentrations in Animal Cells

V-Class H^+ ATPases Maintain the Acidity of Lysosomes and Vacuoles

ABC Proteins Export a Wide Variety of Drugs and Toxins from the Cell

Certain ABC Proteins "Flip" Phospholipids and Other Lipid-Soluble Substrates from One Membrane Leaflet to the Other

The ABC Cystic Fibrosis Transmembrane Regulator Is a Chloride Channel, Not a Pump

11.4 Nongated Ion Channels and the Resting Membrane Potential

Selective Movement of Ions Creates a Transmembrane Electric Gradient

The Resting Membrane Potential in Animal Cells Depends Largely on the Outward Flow of K^+ Ions Through Open K^+ Channels

Ion Channels Are Selective for Certain Ions by Virtue of a Molecular Selectivity Filter

Patch Clamps Permit Measurement of Ion Movements Through Single Channels

Novel Ion Channels Can Be Characterized by a Combination of Oocyte Expression and Patch Clamping

11.5 Cotransport by Symporters and Antiporters

Na^+ Entry into Mammalian Cells Is Thermodynamically Favored

Na^+-Linked Symporters Enable Animal Cells to Import Sugars Including Glucose and Galactose as Well as Amino Acids Against High Concentration Gradients

A Bacterial Na^+/Amino Acid Symporter Reveals How Symport Works

A Na^+-Linked Ca^{2+} Antiporter Regulates the Strength of Cardiac Muscle Contraction

Several Cotransporters Regulate Cytosolic pH

An Anion Antiporter Is Essential for Transport of CO_2 by Erythrocytes

Numerous Transport Proteins Enable Plant Vacuoles to Accumulate Metabolites and Ions

11.6 Transcellular Transport

Multiple Transport Proteins Are Needed to Move Glucose and Amino Acids Across Epithelia

Simple Rehydration Therapy Depends on the Osmotic Gradient Created by Absorption of Glucose and Na^+

Parietal Cells Acidify the Stomach Contents While Maintaining a Neutral Cytosolic pH

Bone Resorption Requires the Coordinated Function of a V-Class Proton Pump and a Specific Chloride Channel

12 Cellular Energetics

12.1 Chemiosmosis, Electron Transport, the Proton-Motive Force, and ATP Synthesis

12.2 First Step of Harvesting Energy from Glucose: Glycolysis

- During Glycolysis (Stage I), Cytosolic Enzymes Convert Glucose to Pyruvate
- The Rate of Glycolysis Is Adjusted to Meet the Cell's Need for ATP
- Glucose Is Fermented When Oxygen Is Scarce

12.3 The Structure of Mitochondria

- Mitochondria Are Abundant, Multifunctional Organelles
- Mitochondria Have Two Structurally and Functionally Distinct Membranes
- Mitochondria Contain DNA and Evolved from a Single Endosymbiotic Event Involving Alphaproteobacterium
- The Size, Structure, and Coding Capacity of mtDNA Vary Considerably Among Organisms
- Mitochondrial DNA Is Located in the Matrix and Transferred During Mitosis to Daughter Cells by Cytoplasmic Inheritance
- Products of Mitochondrial Genes Are Not Exported
- Mitochondrial Genetic Codes Can Differ from the Standard Nuclear Code
- Mutations in Mitochondrial DNA Cause Several Genetic Diseases in Humans

12.4 The Dynamics of Mitochondria and Mitochondrial-ER Membrane Contact Sites

Mitochondria Are Dynamic Organelles

Mitochondrial Function and Dynamics Can Depend on Direct Contacts with Other Organelles

12.5 The Citric Acid Cycle and Fatty Acid Oxidation

In the First Part of Stage II, Pyruvate Is Converted to Acetyl CoA and High-Energy Electrons

In the Second Part of Stage II, the Citric Acid Cycle Oxidizes the Acetyl Group in Acetyl CoA to CO_2 and Generates High-Energy Electrons

Transporters in the Inner Mitochondrial Membrane Help Maintain Appropriate Cytosolic and Matrix Concentrations of NAD^+ and NADH

Mitochondrial Oxidation of Fatty Acids Generates ATP

Peroxisomal Oxidation of Fatty Acids Generates No ATP

12.6 The Electron-Transport Chain and Generation of the Proton-Motive Force

Oxidation of NADH and $FADH_2$ Releases a Substantial Amount of Energy

Electron Transport in Mitochondria Is Coupled to Proton Pumping

Electrons Release Energy as They Flow Downhill Through a Series of Electron Carriers

Four Large Multiprotein Complexes (I–IV) Couple Electron Transport to Proton Pumping Across the Inner Mitochondrial Membrane

The Reduction Potentials of Electron Carriers in the Electron-Transport Chain Favor Electron Flow from NADH to O_2

The Multiprotein Complexes of the Electron-Transport Chain Assemble into Supercomplexes

Reactive Oxygen Species Are By-Products of Electron Transport

Experiments Using Purified Electron-Transport Chain Complexes Established the Stoichiometry of Proton Pumping

The Proton-Motive Force in Mitochondria Is Due Largely to a Voltage Gradient Across the Inner Membrane

12.7 Harnessing the Proton-Motive Force to Synthesize ATP

The Mechanism of ATP Synthesis Is Shared Among Bacteria, Mitochondria, and Chloroplasts

ATP Synthase Comprises F_0 and F_1 Multiprotein Complexes

Rotation of the F_1 γ Subunit, Driven by Proton Movement Through F_0, Powers ATP Synthesis

Multiple Protons Must Pass Through ATP Synthase to Synthesize One ATP

F_0 c Ring Rotation Is Driven by Protons Flowing Through Transmembrane Channels

ATP-ADP Exchange and Phosphate Transport Across the Inner Mitochondrial Membrane Are Required to Supply ADP and Phosphate for ATP Synthesis

The Rate of Mitochondrial Oxidation Normally Depends on ADP Levels

Mitochondria in Brown Fat Use the Proton-Motive Force to Generate Heat

12.8 Chloroplasts and Photosynthesis

Thylakoid Membranes in Chloroplasts Are the Sites of Photosynthesis in Plants

Chloroplasts Contain Large DNAs Often Encoding More Than a Hundred Proteins

Light Absorption by Photosystems in Chloroplasts Provides the Energy That Drives the Synthesis of NADPH and ATP and the Generation of O_2 from H_2O

Three of the Four Stages in Photosynthesis Occur on the Thylakoid Membrane and Only During Illumination

Stages 1 and 2 of Photosynthesis Convert Sunlight into High Energy Electrons That Generate a Proton-Motive Force and NADPH

Core Antenna Complexes and Light-Harvesting Complexes Increase the Efficiency of Photosynthesis

Multiple Mechanisms Protect Cells Against Damage from Reactive Oxygen Species During Photoelectron Transport

12.9 Use of Light Energy to Generate Molecular Oxygen, NADPH, and ATP in Stages 1–3 of Photosynthesis

The First Three Stages of Photosynthesis

Relative Activities of Photosystems I and II Are Regulated

12.10 ATP and NADPH Drive Carbon Fixation in the Calvin Cycle and Carbohydrate Synthesis in Stage 4 of Photosynthesis

Rubisco Fixes CO_2 in the Chloroplast Stroma

Photorespiration Competes with Carbon Fixation and Is Reduced in C_4 Plants

13 Moving Proteins into Membranes and Organelles

13.1 Targeting Proteins to and Across the ER Membrane

Pulse-Chase Experiments with Purified ER Membranes Demonstrated That Secreted Proteins Cross the ER Membrane

A Hydrophobic N-Terminal Signal Sequence Targets Nascent Secretory Proteins to the ER

Cotranslational Translocation Is Initiated by Two GTP-Hydrolyzing Proteins

Passage of Growing Polypeptides Through the Translocon Is Driven by Translation

ATP Hydrolysis Powers Post-Translational Translocation of Some Secretory Proteins in Yeast

13.2 Insertion of Membrane Proteins into the ER

Several Topological Classes of Integral Membrane Proteins Are Synthesized on the ER

Internal Stop-Transfer Anchor and Signal-Anchor Sequences Determine Topology of Single-Pass Proteins

Type IV (Multipass) Proteins

A Phospholipid Anchor Tethers Some Cell-Surface Proteins to the Membrane

The Topology of a Membrane Protein Can Often Be Deduced from Its Sequence

13.3 Protein Modifications, Folding, and Quality Control in the ER

A Preformed *N*-Linked Oligosaccharide Is Added to Many Proteins in the Rough ER

Oligosaccharide Side Chains May Promote Folding and Stability of Glycoproteins

Disulfide Bonds Are Formed and Rearranged by Proteins in the ER Lumen

Chaperones and Other ER Proteins Facilitate Folding and Assembly of Proteins

Improperly Folded Proteins in the ER Induce Expression of Protein-Folding Catalysts

Unassembled or Misfolded Proteins in the ER Are Often Transported to the Cytosol for Degradation

13.4 Targeting of Proteins to Mitochondria and Chloroplasts

Amphipathic N-Terminal Targeting Sequences Direct Proteins to the Mitochondrial Matrix

Mitochondrial Protein Import Requires Outer-Membrane Receptors and Translocons in Both Membranes

Studies with Chimeric Proteins Demonstrate Important Features of Mitochondrial Protein Import

Three Energy Inputs Are Needed to Import Proteins into Mitochondria

Multiple Signals and Pathways Target Proteins to Submitochondrial Compartments

Import of Chloroplast Stromal Proteins Is Similar to Import of Mitochondrial Matrix Proteins

Proteins Are Targeted to Thylakoids by Mechanisms Related to Bacterial Protein Translocation

13.5 Targeting of Peroxisomal Proteins

A Cytosolic Receptor Targets Proteins with an SKL Sequence at the C-Terminus to the Peroxisomal Matrix

Peroxisomal Membrane and Matrix Proteins Are Incorporated by Different Pathways

13.6 Transport into and out of the Nucleus

Large and Small Molecules Enter and Leave the Nucleus via Nuclear Pore Complexes

Nuclear Transport Receptors Escort Proteins Containing Nuclear-Localization Signals into the Nucleus

A Second Type of Nuclear Transport Receptor Escorts Proteins Containing Nuclear-Export Signals out of the Nucleus

Most mRNAs Are Exported from the Nucleus by a Ran-Independent Mechanism

14 Vesicular Traffic, Secretion, and Endocytosis

14.1 Techniques for Studying the Secretory Pathway

Transport of a Protein Through the Secretory Pathway Can Be Assayed in Live Cells

Yeast Mutants Define Major Stages and Components of Vesicular Transport

Cell-Free Transport Assays Allow Dissection of Individual Steps in Vesicular Transport

14.2 Molecular Mechanisms of Vesicle Budding and Fusion

Assembly of a Protein Coat Drives Vesicle Formation and Selection of Cargo Molecules

A Conserved Set of GTPase Switch Proteins Controls the Assembly of Different Vesicle Coats

Targeting Sequences on Cargo Proteins Make Specific Molecular Contacts with Coat Proteins

Rab GTPases Control Docking of Vesicles on Target Membranes

Paired Sets of SNARE Proteins Mediate Fusion of Vesicles with Target Membranes

Dissociation of SNARE Complexes After Membrane Fusion Is Driven by ATP Hydrolysis

14.3 Early Stages of the Secretory Pathway

COPII Vesicles Mediate Transport from the ER to the Golgi

COPI Vesicles Mediate Retrograde Transport Within the Golgi and from the Golgi to the ER

Anterograde Transport Through the Golgi Occurs by Cisternal Maturation

14.4 Later Stages of the Secretory Pathway

Vesicles Coated with Clathrin and Adapter Proteins Mediate Transport from the *trans*-Golgi

Dynamin Is Required for Pinching Off of Clathrin-Coated Vesicles

Mannose 6-Phosphate Residues Target Resident Enzymes to Lysosomes

Study of Lysosomal Storage Diseases Revealed Key Components of the Lysosomal Sorting Pathway

Protein Aggregation in the *trans*-Golgi May Function in Sorting Proteins to Regulated Secretory Vesicles

Some Proteins Undergo Proteolytic Processing After Leaving the *trans*-Golgi

Distinct Pathways Sort Membrane Proteins to the Apical or Basolateral Region of Polarized Cells

14.5 Receptor-Mediated Endocytosis

Cells Take Up Lipids from the Blood in the Form of Large, Well-Defined Lipoprotein Complexes

Receptors for Macromolecular Ligands Contain Sorting Signals That Target Them for Endocytosis

The Acidic pH of Late Endosomes Causes Most Receptor-Ligand Complexes to Dissociate

Receptor-Mediated Endocytosis Can Down-Regulate Signaling Receptors

14.6 Directing Membrane Proteins and Cytosolic Materials to the Lysosome for Degradation

Multivesicular Endosomes Segregate Membrane Proteins Destined for the Lysosomal Membrane from Proteins Destined for Lysosomal Degradation

Retroviruses Bud from the Plasma Membrane by a Process Similar to Formation of Multivesicular Endosomes

The Autophagic Pathway Delivers Cytosolic Proteins or Entire Organelles to Lysosomes

15 Receptors, Hormones, and Cell Signaling

15.1 Signal Transduction Pathways: From Extracellular Signal to Cellular Response

Signaling Molecules Can Act Locally or at a Distance

Signal Transduction Pathways Can Produce Rapid, Short-Term or Slow, Long-Term Changes in Cells, or Both

Receptors Are Allosteric Proteins That Activate Signal Transduction Pathways

Receptors Can Be in the Cytosol, Nucleus, or on the Cell Surface Membrane

Most Receptors Bind Only a Single Type of Ligand or a Group of Closely Related Ligands

Most Receptors Bind Their Ligands with High Affinity

Second Messengers Are Used in Most Signal Transduction Pathways

Protein Kinases and Phosphatases Participate in Signal Transduction Pathways by Covalently Modifying and Thus Activating or Inhibiting a Wide Variety of Proteins That Control Cellular States

GTP-Binding Proteins Are Frequently Used in Signal Transduction Pathways as On/Off Switches

Signal Amplification and Feedback Repression Characterize Most Signal Transduction Pathways

15.2 Studying Cell-Surface Receptors and Signal Transduction Proteins

Binding Assays Are Used to Detect Receptors and Determine Their Affinity and Specificity for Ligands

Near-Maximal Cellular Response to a Signaling Molecule Usually Does Not Require Activation of All Receptors

Sensitivity of a Cell to External Signals Is Determined by the Number of Cell-Surface Receptors and Their Affinity for Ligand

Chemical Analogs of Signaling Molecules Are Used to Study Receptors and Are Widely Used as Drugs

Receptors Can Be Purified by Affinity Chromatography Techniques

Immunoprecipitation Assays and Affinity Techniques Can Be Used to Study the Activity of Protein Kinases

Immunoprecipitation of Kinases

Western Blotting with a Monoclonal Antibody Specific for a Phosphorylated Amino Acid in a Protein

GTP-Binding Signal Transduction Proteins Can Be Isolated and Their Activities Measured Using Pull-Down Assays

Concentrations of Free Ca^{2+} in the Mitochondrial Matrix, ER, and Cytosol Can Be Measured with Targeted Fluorescent Proteins

15.3 Structure and Mechanism of G Protein–Coupled Receptors

All G Protein–Coupled Receptors Share the Same Basic Structure

Ligand-Activated G Protein–Coupled Receptors Catalyze Exchange of GTP for GDP on the α Subunit of a Heterotrimeric G Protein

Different G Proteins Are Activated by Different GPCRs and in Turn Regulate Different Effector Proteins

Analysis of GPCRs Has Identified Important Human Hormones

15.4 Regulating Metabolism of Many Cells: G Protein–Coupled Receptors That Activate or Inhibit Adenylyl Cyclase

Adenylyl Cyclase Is Stimulated and Inhibited by Different Receptor-Ligand Complexes

cAMP Activates Protein Kinase A by Releasing Its Inhibitory Subunits

Glycogen Catabolism Is Stimulated by Hormone-Induced Activation of PKA

Signal Amplification Occurs in the cAMP-PKA Glycogen Degradation Pathway

cAMP-Mediated Activation of PKA Produces Diverse Responses in Different Cell Types

CREB Links cAMP and PKA to Activation of Gene Transcription

Anchoring Proteins Localize Effects of cAMP to Specific Regions of the Cell

Multiple Feedback Mechanisms Suppress Signaling by the GPCR/cAMP/PKA Pathway

15.5 Regulating Protein Secretion and Muscle Contraction: Ca^{2+} Ions as Second Messengers in Multiple Signal Transduction Pathways

Products of the Hydrolysis of the Membrane Lipid Phosphatidylinositol 4,5-Bisphosphate by Phospholipase C Elevate Cytosolic Ca^{2+} Levels

Ca^{2+} Release from the ER Triggered by IP_3

IP_3-triggered Ca^{2+} Transport from the ER to the Mitochondrial Matrix

The Store-Operated Ca^{2+} Channel in the Plasma Membrane

Feedback Loops in ER and Cytosol Cycling of Ca^{2+} Trigger Oscillations in the Cytosolic Ca^{2+} Concentration

DAG Activates Protein Kinase C

Integration of Ca^{2+} and cAMP Second Messengers Regulates Glycogenolysis

15.6 Vision: How the Eye Senses Light

Light Activates Rhodopsin in Rod Cells of the Eye

Activation of Rhodopsin by Light Leads to Closing of cGMP-Gated Cation Channels

Signal Amplification Makes the Rhodopsin Signal Transduction Pathway Exquisitely Sensitive

Rapid Termination of the Rhodopsin Signal Transduction Pathway Is Essential for the Temporal Resolution of Vision

Termination of the Signal from Light-Activated Rhodopsin (R*) by Rhodopsin Phosphorylation and Binding of Arrestin

Termination of the Signal from Activated $G_{\alpha t}$·GTP by GTP Hydrolysis

Rod Cells Adapt to Varying Levels of Ambient Light by Intracellular Trafficking of Arrestin and Transducin

16 Growth Factor and Cytokine Signaling Pathways That Control Gene Expression

16.1 Growth Factors and Their Receptor Tyrosine Kinases

Binding of Ligand to the Extracellular Domain of an RTK Leads to Dimerization and Activation of Its Intrinsic Cytosolic Tyrosine Kinase

Homo- and Hetero-Oligomers of Epidermal Growth Factor Receptors Bind Members of the Epidermal Growth Factor Family

EGF Receptor Homodimers

EGF Receptor Heterodimers with HER2

Ligand Binding to the EGF Receptor and Receptor Dimerization Results in the Formation of an Active Asymmetric Kinase Domain Dimer

Signal Transduction After Activation of RTKs: Phosphotyrosine Residues on the Receptor Are Binding Surfaces for Multiple Proteins with SH2 Domains

Receptor-Mediated Endocytosis and Lysosomal Degradation Squelch Signaling from RTKs

16.2 The Ras/MAP Kinase Signal Transduction Pathway

Ras, a GTPase Switch Protein, Operates Downstream of Most RTKs and Cytokine Receptors

Receptor Tyrosine Kinases Are Linked to Ras by Adapter Proteins

Binding of Sos to Inactive Ras Causes a Conformational Change That Triggers an Exchange of GTP for GDP

Signals Pass from Activated Ras to a Cascade of Protein Kinases Ending with MAP Kinase

MAP Kinase Regulates the Activity of Many Transcription Factors Controlling Early Response Genes

Multiple Feedback Mechanisms Restrain MAP Kinase Activation

Scaffold Proteins Isolate Distinct MAP Kinase Pathways in the Same Cell from One Another

16.3 Phosphoinositide Signal Transduction Pathways

Phospholipase C_γ Is Activated by Many RTKs and Cytokine Receptors

Recruitment of PI-3 Kinase to Activated Receptors Leads to Accumulation of Phosphatidylinositol-3-Phosphates in the Plasma Membrane and to Activation of Several Downstream Kinases

Activated Protein Kinase B Induces Many Cellular Responses

The PI-3 Kinase Pathway Is Negatively Regulated by PTEN Phosphatase

16.4 Cytokines, Cytokine Receptors, and the JAK/STAT Signaling Pathway

Cytokines Regulate the Development and Function of Many Cell Types

Binding of a Cytokine to Its Receptor Activates One or More Tightly Bound JAK Protein Tyrosine Kinases

JAK Kinases Phosphorylate and Activate STAT Transcription Factors

Multiple Mechanisms Suppress Signaling from Cytokine Receptors

Phosphotyrosine Phosphatases

SOCS Proteins

16.5 The TGF-β Family of Growth Factors, Their Receptor Serine Kinases, and the Smad Transcription Factors They Activate

TGF-β Proteins Are Stored in an Inactive Form in the Extracellular Matrix

Three Separate TGF-β Receptor Proteins Participate in Binding TGF-β and Activating Signal Transduction

Activated RI TGF-β Receptors Phosphorylate Smad Transcription Factors

The R-Smad/co-Smad Complex Activates Expression of Different Genes in Different Cell Types

Negative Feedback Loops Restrain TGF-β/Smad Signaling

16.6 Signal Transduction Pathways That Utilize Regulated, Site-Specific Protein Cleavage: Notch/Delta and EGF Precursors

On Binding Delta, the Notch Receptor Is Cleaved, Releasing a Component Transcription Factor

Metalloproteases Catalyze Cleavage of Many Signaling Proteins from the Cell Surface

16.7 Signal Transduction Pathways That Utilize Proteasomal Degradation of Signaling Components: Wnt, Hedgehog, and the Many Hormones That Activate NF-κB

Wnt Signaling Prevents Destruction of a Transcription Factor by a Cytosolic Protein Complex

Concentration Gradients of Wnt Protein Are Essential for Many Steps in Development

Hedgehog Signaling Relieves Repression of Target Gene Expression

Processing of Hh Precursor Protein

The Hh Receptors Patched and Smoothened and the Downstream Signaling Pathway Were Initially Elucidated by

Genetic Studies of *Drosophila* Development

Feedback Regulation of Hh Signaling

Hedgehog Signaling in Vertebrates Requires Primary Cilia

Degradation of an Inhibitor Protein Activates the NF-κB Transcription Factor

Enormous Signalsomes with Polyubiquitin Chain Scaffolds Link Many Cell Surface Receptors to Downstream Proteins in the NF-κB Pathway

17 Cell Organization and Movement I: Microfilaments

17.1 Microfilaments and Actin Structures

Actin Is Ancient, Abundant, and Highly Conserved

G-Actin Monomers Assemble into Long, Helical F-Actin Polymers

F-Actin Has Structural and Functional Polarity

17.2 Dynamics of Actin Filaments

Actin Polymerization In Vitro Proceeds in Three Steps

Actin Filaments Grow Faster at (+) Ends than at (−) Ends

Actin Filament Treadmilling Is Accelerated by Profilin and Cofilin

Thymosin-β_4 Provides a Reservoir of Actin for Polymerization

Capping Proteins Block Assembly and Disassembly at Actin Filament Ends

17.3 Mechanisms of Actin Filament Assembly

Formins Assemble Unbranched Filaments

The Arp2/3 Complex Nucleates Branched Filament Assembly

Intracellular Movements Can Be Powered by Actin Polymerization

Microfilaments Function in Endocytosis

Toxins That Perturb the Pool of Actin Monomers Are Useful for Studying Actin Dynamics

17.4 Organization of Actin-Based Cellular Structures

Cross-Linking Proteins Organize Actin Filaments into Bundles or Networks

Adapter Proteins Link Actin Filaments to Membranes

17.5 Myosins: Actin-Based Motor Proteins

Myosins Have Head, Neck, and Tail Domains with Distinct Functions

Myosins Make Up a Large Family of Mechanochemical Motor Proteins

Conformational Changes in the Myosin Head Couple ATP Hydrolysis to Movement

Myosin Heads Take Discrete Steps Along Actin Filaments

17.6 Myosin-Powered Movements

Myosin Thick Filaments and Actin Thin Filaments in Skeletal Muscle Slide Past Each Other During Contraction

Skeletal Muscle Is Structured by Stabilizing and Scaffolding Proteins

Contraction of Skeletal Muscle Is Regulated by Ca^{2+} and Actin-Binding Proteins

Actin and Myosin II Form Contractile Bundles in Nonmuscle Cells

Myosin-Dependent Mechanisms Regulate Contraction in Smooth Muscle and Nonmuscle Cells

Myosin V Carries Vesicles Along Actin Filaments

17.7 Cell Migration: Mechanism, Signaling, and Chemotaxis

Cell Migration Coordinates Force Generation with Cell Adhesion and Membrane Recycling

The Small GTP-Binding Proteins Cdc42, Rac, and Rho Control Actin Organization

Cell Migration Involves the Coordinate Regulation of Cdc42, Rac, and Rho

Migrating Cells Are Steered by Chemotactic Molecules

18 Cell Organization and Movement II: Microtubules and Intermediate Filaments

18.1 Microtubule Structure and Organization

Microtubule Walls Are Polarized Structures Built from αβ-Tubulin Dimers

Microtubules Are Assembled from MTOCs to Generate Diverse Configurations

18.2 Microtubule Dynamics

Individual Microtubules Exhibit Dynamic Instability

Localized Assembly and *Search and Capture* Help Organize Microtubules

Drugs Affecting Tubulin Polymerization Are Useful Experimentally and in Treatment of Diseases

18.3 Regulation of Microtubule Structure and Dynamics

Microtubules Are Stabilized by Side-Binding Proteins

+TIPs Regulate the Properties and Functions of the Microtubule (+) End

Other End-Binding Proteins Also Promote Microtubule Disassembly

Severing Proteins Also Regulate Microtubule Dynamics

18.4 Kinesins and Dyneins: Microtubule-Based Motor Proteins

Organelles in Axons Are Transported Along Microtubules in Both Directions

Kinesin-1 Powers Anterograde Transport of Vesicles Down Axons Toward the (+) Ends of Microtubules

The Kinesins Form a Large Protein Superfamily with Diverse Functions

Kinesin-1 Is a Processive Motor

Dynein Motors Transport Organelles Toward the (–) Ends of Microtubules

Kinesins and Dyneins Cooperate in the Transport of Organelles Throughout the Cell

Tubulin Modifications Distinguish Different Classes of Microtubules and Their Accessibility to Motors

18.5 Cilia and Flagella: Microtubule-Based Surface Structures

Eukaryotic Cilia and Flagella Contain Long Doublet Microtubules Bridged by Dynein Motors

Ciliary and Flagellar Beating Are Produced by Controlled Sliding of Outer Doublet Microtubules

Intraflagellar Transport Moves Material Up and Down Cilia and Flagella

Primary Cilia Are Sensory Organelles on Interphase Cells

Defects in Primary Cilia Underlie Many Diseases

18.6 Mitosis

Centrosomes Duplicate Early in the Cell Cycle in Preparation for Mitosis

Mitosis Can Be Divided into Five Stages

The Mitotic Spindle Contains Three Classes of Microtubules

Microtubule Dynamics Increase Dramatically in Mitosis

Chromosomes Are Captured and Oriented During Prometaphase

Duplicated Chromosomes Are Aligned by Motors and Microtubule Dynamics

The Chromosomal Passenger Complex Regulates Microtubule Attachment at Kinetochores

Anaphase A Moves Chromosomes to Poles by Microtubule Shortening

Anaphase B Separates Poles by the Combined Action of Kinesins and Dynein

The Spindle Is Centered and Oriented by a Dynein/Dynactin-Dependent Pathway

Cytokinesis Splits the Duplicated Cell in Two

Plant Cells Reorganize Their Microtubules and Build a New Cell Wall in Mitosis

18.7 Intermediate Filaments

Intermediate Filaments Are Assembled from Subunit Dimers

Intermediate Filaments Are Dynamic

Cytoplasmic Intermediate Filament Proteins Are Expressed in a Tissue-Specific Manner

Lamins Line the Inner Nuclear Envelope to Provide Organization and Rigidity to the Nucleus

Lamins Are Reversibly Disassembled by Phosphorylation During Mitosis

18.8 Coordination and Cooperation Between Cytoskeletal Elements

Intermediate Filament–Associated Proteins Contribute to Cellular Organization

Microfilaments and Microtubules Cooperate to Transport Melanosomes

Cdc42 Coordinates Microtubules and Microfilaments During Cell Migration

Advancement of Neural Growth Cones Is Coordinated by Microfilaments and Microtubules

19 The Eukaryotic Cell Cycle

19.1 Overview of the Cell Cycle

G_1 Controls Entry into S Phase

G_2 Phase Readies the Cell for Mitosis and Cell Division

Mitosis and Cytokinesis Occur During M-Phase

19.2 Model Organisms and Methods of Studying the Cell Cycle

Budding and Fission Yeasts Are Powerful Systems for Genetic Analysis of the Cell Cycle

Frog Oocytes and Early Embryos Facilitate Biochemical Characterization of the Cell Cycle Machinery

The Study of Tissue Culture Cells Uncovers Cell Cycle Regulation in Mammals

Researchers Use Multiple Tools to Study the Cell Cycle

19.3 Cell Cycle Progression and Control: Feedback Loops and Post-Translational Modification

Cyclin-Dependent Kinases Are Small Protein Kinases That Require a Regulatory Cyclin Subunit for Their Activity

Cyclins Determine the Activity of CDKs

CDKs Are Regulated by Activating and Inhibitory Phosphorylation

CDK Inhibitors Provide Additional Control of Cyclin-CDK Activity

Cyclin Levels Are Regulated by Transcriptional Activation and Ubiquitin-Mediated Protein Degradation

Phosphoserine/Threonine-Binding Domains Build Feedback Loops That Coordinate CDK Activation and Cell Cycle Progression

Mass Spectrometry Studies and Genetically Engineered CDKs Led to the Discovery of New CDK Substrates and Functions

19.4 The Transition from G_1 into S Phase and DNA Replication

The G_1/S Transition in Budding Yeast Is Controlled by Cyclin-CDK Complexes

The G_1–S Phase Transition in Metazoans Involves Cyclin-CDK Control of the E2F Transcription Factor Through Its Regulator Rb

Extracellular Signals Govern Cell Cycle Entry

Degradation of an S Phase CDK Inhibitor Triggers DNA Replication

Replication at Each Origin Is Initiated Once and Only Once During the Cell Cycle

Duplicated DNA Strands Become Linked During Replication

19.5 The G_2/M Transition and the Irreversible Engine of Mitosis

Precipitous Activation of Mitotic CDKs by Positive Feedback Loops Initiates Mitosis

Mitotic CDKs Promote Nuclear Envelope Breakdown

Centrosomes Duplicate During S phase and Separate During Mitosis

Mitotic CDKs, Polo-like Kinases, and Aurora Kinases Drive Assembly of a Mitotic Spindle That Attaches to the Kinetochores of Condensed Chromosomes

Chromosome Condensation Facilitates Chromosome Segregation

19.6 The Mitotic Spindle, Chromosome Segregation, and Exit from Mitosis

Separase-Mediated Cleavage of Cohesins Initiates Chromosome Segregation

APC/C Activates Separase Through Securin Ubiquitinylation

Mitotic CDK Inactivation and Protein Dephosphorylation Triggers Exit from Mitosis

Cytokinesis Creates Two Daughter Cells

19.7 Surveillance Mechanisms in Cell Cycle Regulation

The DNA Damage Response System Halts Cell Cycle Progression and Recruits DNA Repair Machinery When DNA Is Compromised

The Spindle Assembly Checkpoint Pathway Prevents Chromosome Segregation Until Chromosomes Are Accurately Attached to the Mitotic Spindle

19.8 Meiosis: A Special Type of Cell Division

Extracellular and Intracellular Cues Regulate Germ Cell Formation

Several Features Distinguish Meiosis from Mitosis

Recombination and a Meiosis-Specific Cohesin Subunit Are Necessary for the Specialized Chromosome Segregation in Meiosis I

Co-orienting Sister Kinetochores Is Critical for Meiosis I Chromosome Segregation

Part IV Cell Growth and Differentiation

20 Integrating Cells into Tissues

20.1 Cell-Cell and Cell–Extracellular Matrix Adhesion: An Overview

Cell-Adhesion Molecules Bind to One Another and to Intracellular Proteins

The Extracellular Matrix Participates in Adhesion, Signaling, and Other Functions

The Evolution of Multifaceted Adhesion Molecules Enabled the Evolution of Diverse Animal Tissues

Cell-Adhesion Molecules Mediate Mechanotransduction

20.2 Cell-Cell and Cell–Extracellular Matrix Junctions and Their Adhesion Molecules

Epithelial Cells Have Distinct Apical, Lateral, and Basal Surfaces

Three Types of Junctions Mediate Many Cell-Cell and Cell-Matrix Interactions

Cadherins Mediate Cell-Cell Adhesions in Adherens Junctions and Desmosomes

Integrins Mediate Cell-Matrix Adhesions, Including Those in Epithelial-Cell Hemidesmosomes

Tight Junctions Seal Off Body Cavities and Restrict Diffusion of Membrane Components

Gap Junctions Composed of Connexins Allow Small Molecules to Pass Directly Between the Cytosols of Adjacent Cells

Tunneling Nanotubes Can Mediate Metabolic Coupling and Transfer Organelles Between Animal Cells

20.3 The Extracellular Matrix I: The Basal Lamina

The Basal Lamina Provides a Foundation for Assembly of Cells into Tissues

Laminin, a Multi-Adhesive Matrix Protein, Helps Cross-Link Components of the Basal Lamina

Sheet-Forming Type IV Collagen Is a Major Structural Component of the Basal Lamina

Perlecan, a Proteoglycan, Cross-Links Components of the Basal Lamina and Cell-Surface Receptors

20.4 The Extracellular Matrix II: Connective Tissue

Fibrillar Collagens Are the Major Fibrous Proteins in the ECM of Connective Tissues

Fibrillar Collagen Is Secreted and Assembled into Fibrils Outside the Cell

Type I and II Collagens Associate with Nonfibrillar Collagens to Form Diverse Structures

Proteoglycans and Their Constituent GAGs Play Diverse Roles in the ECM

Hyaluronan Resists Compression, Facilitates Cell Migration, and Gives Cartilage Its Gel-Like Properties

Fibronectins Connect Cells and ECM, Influencing Cell Shape, Differentiation, and Movement

Elastic Fibers Permit Many Tissues to Undergo Repeated Stretching and Recoiling

Metalloproteases Remodel and Degrade the Extracellular Matrix

20.5 Adhesive Interactions in Motile and Nonmotile Cells

Integrins Mediate Adhesion and Relay Signals Between Cells and Their Three-Dimensional Environment

Regulation of Integrin-Mediated Adhesion and Signaling Controls Cell Function and Movement

Connections Between the ECM and Cytoskeleton Are Defective in Muscular Dystrophy

IgCAMs Mediate Cell-Cell Adhesion in Neural and Other Tissues

Leukocyte Movement into Tissues Is Orchestrated by a Precisely Timed Sequence of Adhesive Interactions

20.6 Plant Tissues

The Plant Cell Wall, a Plant's ECM, Is a Laminate of Cellulose Fibrils in a Matrix of Polysaccharides and Glycoproteins

Loosening of the Cell Wall Permits Plant Cell Growth

Plasmodesmata Directly Connect the Cytosols of Adjacent Cells

The Molecules That Plants Depend on for Adhesion and Mechanotransduction Differ from Those in Animals

21 Responding to the Cellular Environment

21.1 Regulating Blood Glucose Level

Insulin and Glucagon Work Together to Maintain a Stable Blood Glucose Level

A Rise in Blood Glucose Triggers Insulin Secretion from the β Islet Cells

In Fat and Muscle Cells, Insulin Triggers Fusion of Intracellular Vesicles Containing the GLUT4 Glucose Transporter with the Plasma Membrane, Thus Increasing the Rate of Glucose Uptake

In the Liver, Insulin Inhibits Glucose Synthesis, Accelerates the Rate of Glycolysis, and Enhances Storage of Glucose as Glycogen

21.2 Integrating Cell Growth Signals with Nutrient and Energy Levels

The Active mTORC1 Complex Activates Many Anabolic Signal Transduction Pathways

mTORC1 Kinase Activation Requires Amino Acids, a High ATP:AMP Ratio, and Activation of Signal Transduction Pathways Downstream of Growth-Factor Receptors

21.3 Responding to Changes in the Levels of Cholesterol and Unsaturated Fatty Acids

Fatty Acid and Cholesterol Biosynthesis as Well as Cholesterol Import Are Regulated at the Level of Gene Transcription

The Endoplasmic Reticulum SCAP Protein Senses the Level of Cellular Cholesterol

Regulated Intramembrane Proteolysis of SREBP in the Golgi Releases a bHLH Transcription Factor That Acts to Maintain Appropriate Phospholipid and Cholesterol Levels

21.4 Responding to Low Oxygen

Induction of the Erythropoietin Gene at Low Oxygen Levels

Oxygen Sensing and Regulated Hif-1α Expression Is a Property of All Nucleated Mammalian Cells

Hif-1α Function and Stability Are Blocked at Ambient Oxygen Levels

A Conserved Family of Oxygen-Sensitive Transcription Factors Found in Plants and Animals Is Regulated by Post-Translational Addition of an Arginine Residue

21.5 Responding to Elevated Temperatures

The Heat-Shock Response Is Induced by Unfolded Polypeptide Chains

The Heat-Shock Response Is Regulated Primarily by Related Transcription Factors in All Eukaryotes Called *Heat-Shock Factors*, Including HSF1 in Humans

21.6 Sensing Night and Day: Circadian Rhythms

The Circadian Clock in Most Organisms Relies on a Negative Feedback Loop

The Circadian Clock in Bacteria: A Different Solution

Suprachiasmatic Nucleus: The Master Clock in Mammals

21.7 Sensing and Responding to the Physical Environment

The Hippo Kinase Cascade Pathway in *Drosophila* and Mammals

Regulation of the Hippo Kinase Cascade by Cell Interactions with the Extracellular Matrix and by Tension on Actin Filaments

The Hippo Pathway and Early Embryogenesis

22 Stem Cells, Cell Asymmetry, and Regulated Cell Death

22.1 Early Mammalian Development, Embryonic Stem Cells, and Induced Pluripotent Stem Cells

Fertilization Unifies the Genome

Cleavage of the Mammalian Embryo Leads to the First Differentiation Events

Pluripotent Cells of the Inner Cell Mass Are the Source of ES Cells

Multiple Factors Control the Pluripotency of ES Cells

Animal Cloning Shows That Epigenetic Changes During Differentiation Can Be Reversed

Somatic Cells Can Generate iPS Cells

Patient-Specific iPS Cells Can Be Used to Develop Potential Treatments for Many Diseases

ES and iPS Cells Can Generate Functional Differentiated Human Cells

22.2 Stem Cells and Niches in Multicellular Organisms

Adult Planarians Contain Pluripotent Stem Cells

Multipotent Somatic Stem Cells Give Rise to Both Stem Cells and Differentiating Cells

Stem Cells for Different Tissues Occupy Sustaining Niches

Germ-Line Stem Cells in Many Organisms Produce Sperm or Oocytes

Intestinal Stem Cells Continuously Generate All the Cells of the Intestinal Epithelium

Wnt and R-Spondins Are Essential for Function of the $Lgr5^+$ Intestinal Stem Cells

Hematopoietic Stem Cells Form All Blood Cells and All Cells of the Immune System

Characterizing Hematopoietic Stem Cells by Transplantation

Niches for Hematopoietic Stem Cells and Many Hematopoietic Progenitor Cells

Regulating the Production of Differentiated Hematopoietic Cells

Meristems Are Niches for Stem Cells in Plants

A Negative Feedback Loop Maintains the Size of the Shoot Apical Stem-Cell Population

The Root Meristem Resembles the Shoot Meristem in Structure and Function

22.3 Mechanisms of Cell Polarity and Asymmetric Cell Division

The Intrinsic Polarity Program Depends on a Positive Feedback Loop Involving Cdc42

Cell Polarization Before Cell Division Follows a Common Hierarchy of Steps

Polarized Membrane Traffic Allows Yeast to Grow Asymmetrically During Mating

The Par Proteins Direct Cell Asymmetry in the Nematode Embryo

The Par Proteins and Other Polarity Complexes Are Involved in Epithelial-Cell Polarity

The Planar Cell Polarity Pathway Orients Cells Within an Epithelium

The Par Proteins Are Involved in Asymmetric Division of Stem Cells

22.4 Cell Death and Its Regulation

Most Programmed Cell Death Occurs Through Apoptosis

Evolutionarily Conserved Proteins Participate in the Apoptotic Pathway

Caspases Amplify the Initial Apoptotic Signal and Destroy Key Cellular Proteins

Phosphatidylserine: an “Eat Me” Signal on the Surface of Apoptotic Cells

Neurotrophins Promote Survival of Neurons

Mitochondria Play a Central Role in Regulation of Apoptosis in Vertebrate Cells

The Pro-Apoptotic Proteins Bax and Bak Form Pores and Holes in the Outer Mitochondrial Membrane

Release of SMAC/DIABLO Proteins from Mitochondria Also Promotes Caspase Activation

Trophic Factors Induce Inactivation of Bad, a Pro-apoptotic BH3-Only Protein

Apoptosis in Vertebrates Is Induced by BH3-Only Pro-apoptotic Proteins That Are Activated by Environmental Stresses

Apoptosis and Necroptosis Can Be Triggered by Tumor Necrosis Factor, Fas Ligand, and Related Death Proteins

23 Cells of the Nervous System

23.1 Neurons and Glia: Building Blocks of the Nervous System

Information Flows Through Neurons from Dendrites to Axons

Information Moves Along Axons as Pulses of Ion Flow Called *Action Potentials*

Information Flows Between Neurons via Synapses

The Nervous System Uses Signaling Circuits Composed of Multiple Types of Neurons

Glial Cells Form Myelin Sheaths and Support Neurons

Neural Stem Cells Form Nerve and Glial Cells in the Central Nervous System

23.2 Voltage-Gated Ion Channels and the Propagation of Action Potentials

The Magnitude of the Action Potential Is Close to E_{Na} and Is Caused by Na^+ Influx Through Open Na^+ Channels

Sequential Opening and Closing of Voltage-Gated Na^+ and K^+ Channels Generate Action Potentials

Action Potentials Are Propagated Unidirectionally Without Diminution

All Voltage-Gated Ion Channels Have Similar Structures

Voltage-Sensing S4 α Helices Move in Response to Membrane Depolarization

Movement of the Channel-Inactivating Segment into the Open Pore Blocks Ion Flow

Myelination Increases the Velocity of Impulse Conduction

Action Potentials "Jump" from Node to Node in Myelinated Axons

Two Types of Glia Produce Myelin Sheaths

Light-Activated Ion Channels and Optogenetics

23.3 Communication at Synapses

Formation of Synapses Requires Assembly of Presynaptic and Postsynaptic Structures

Neurotransmitters Are Transported into Synaptic Vesicles by H^+-Linked Antiport Proteins

Three Pools of Synaptic Vesicles Loaded with Neurotransmitter Are Present in the Presynaptic Terminal

Influx of Ca^{2+} Triggers Release of Neurotransmitters

A Calcium-Binding Protein Regulates Fusion of Synaptic Vesicles with the Plasma Membrane

Fly Mutants Lacking Dynamin Cannot Recycle Synaptic Vesicles

Signaling at Synapses Is Terminated by Degradation or Reuptake of Neurotransmitters

Opening of Acetylcholine-Gated Cation Channels Leads to Muscle Contraction

All Five Subunits in the Nicotinic Acetylcholine Receptor Contribute to the Ion Channel

Nerve Cells Integrate Many Inputs to Make an All-or-None Decision to Generate an Action Potential

Gap Junctions Allow Direct Communication Between Neurons and Between Glia

23.4 Sensing the Environment: Touch, Pain, Taste, and Smell

Mechanoreceptors Are Gated Cation Channels

Pain Receptors Are Also Gated Cation Channels

Five Primary Tastes Are Sensed by Subsets of Cells in Each Taste Bud

The Largest Group of G Protein–Coupled Receptors Detect Odors

Each Olfactory Receptor Neuron Expresses a Single Type of Odorant Receptor

23.5 Forming and Storing Memories

Memories Are Formed by Changing the Number or Strength of Synapses Between Neurons

The Hippocampus Is Required for Memory Formation

Multiple Molecular Mechanisms Contribute to Synaptic Plasticity

Formation of Long-Term Memories Requires Gene Expression

24 Immunology

24.1 Overview of Host Defenses

Pathogens Enter the Body Through Different Routes and Replicate at Different Sites

Cells of the Innate and Adaptive Immune Systems Circulate Throughout the Body and Take Up Residence in Tissues and Lymph Nodes

Mechanical and Chemical Boundaries Form a First Layer of Defense Against Pathogens

Innate Immunity Provides a Second Line of Defense

Inflammation Is a Complex Response to Injury That Encompasses Both Innate and Adaptive Immunity and Helps Destroy Pathogens

Adaptive Immunity, the Third Line of Defense, Exhibits Specificity

24.2 Immunoglobulins: Structure and Function

Immunoglobulins Have a Conserved Structure Consisting of Heavy and Light Chains

Multiple Immunoglobulin Isotypes Exist, Each with Different Functions

Each Naive B Cell Produces a Unique Immunoglobulin

Immunoglobulin Domains Have a Characteristic Fold Composed of β Two Sheets Stabilized by a Disulfide Bond

An Immunoglobulin's Constant Region Determines Its Functional Properties

24.3 Generation of Antibody Diversity and B-Cell Development

A Functional Light-Chain Gene Requires Assembly of V and J Gene Segments

Rearrangement of the Heavy-Chain Locus Involves V, D, and J Gene Segments

Somatic Hypermutation Allows the Generation and Selection of Antibodies with Improved Affinities

B-Cell Development Requires Input from a Pre-B-Cell Receptor

During an Adaptive Response, B Cells Switch from Making Membrane-Bound Ig to Making Secreted Ig

B Cells Can Switch the Isotype of Immunoglobulin They Make

24.4 The MHC and Antigen Presentation

The MHC Determines the Ability of Two Unrelated Individuals of the Same Species to Accept or Reject Grafts

The Killing Activity of Cytotoxic T Cells Is Antigen Specific and MHC Restricted

T Cells with Different Functional Properties Are Guided by Two Distinct Classes of MHC Molecules

MHC Molecules Are Highly Polymorphic, Bind Peptide Antigens, and Interact with the T-Cell Receptor

In Antigen Presentation, Protein Fragments Are Complexed with MHC Products and Posted to the Cell Surface

The Class I MHC Pathway Presents Cytosolic Antigens

The Class II MHC Pathway Presents Antigens Delivered to the Endocytic Pathway

24.5 T Cells, T-Cell Receptors, and T-Cell Development

The Structure of the T-Cell Receptor Resembles the F(ab) Portion of an Immunoglobulin

TCR Genes Are Rearranged in a Manner Similar to Immunoglobulin Genes

Many of the Variable Residues of TCRs Are Encoded in the Junctions Between V, D, and J Gene Segments

Signaling via Antigen-Specific Receptors Triggers Proliferation and Differentiation of T and B Cells

T Cells Capable of Recognizing MHC Molecules Develop Through a Process of Positive and Negative Selection

T Cells Commit to the CD4 or CD8 Lineage in the Thymus

T Cells Require Two Types of Signals for Full Activation

Cytotoxic T Cells Carry the CD8 Co-Receptor and Are Specialized for Killing

T Cells Secrete an Array of Cytokines That Provide Signals to Other Immune-System Cells

Helper T Cells Are Divided into Distinct Subsets Based on Their Cytokine Production and Expression of Surface Markers

Innate Lymphoid Cells Regulate Inflammation and the Overall Immune Response

Leukocytes Move in Response to Chemotactic Cues Provided by Chemokines

24.6 Collaboration of Immune-System Cells in the Adaptive Response

Toll-Like Receptors Perceive a Variety of Pathogen-Derived Macromolecular Patterns

Engagement of Toll-Like Receptors Leads to Activation of Antigen-Presenting Cells

Production of High-Affinity Antibodies Requires Collaboration Between B and T cells

Vaccines Elicit Protective Immunity Against a Variety of Pathogens

The Immune System Defends Against Cancer

25 Cancer

25.1 How Tumor Cells Differ from Normal Cells

The Genetic Makeup of Most Cancer Cells Is Dramatically Altered

Uncontrolled Proliferation Is a Universal Trait of Cancer

Cellular Housekeeping Functions Are Fundamentally Altered in Cancer Cells

Cancer Cells Exhibit Altered Cell-Cell Interactions to Form Heterogeneous Organs

Tumor Growth Requires Formation of New Blood Vessels

Invasion and Metastasis Are Late Stages of Tumorigenesis

25.2 Genetic and Genomic Basis of Cancer

Carcinogens Induce Cancer by Damaging DNA

Some Carcinogens Have Been Linked to Specific Cancers

Familial Syndromes that Cause Loss of DNA Repair Can Lead to Cancer

Somatic Mutations in the DNA Damage Response Pathway Are Oncogenic

Cancer Genome Sequencing Reveals an Enormous Diversity of Somatic Mutations

Oncogenes Were Discovered by Their Association with Tumor Viruses

Single Oncogenic Drivers Can Be Activated by Chromosome Rearrangements

Inherited Predisposition for Cancer Enabled Identification of Some Oncogenic Drivers

Oncogenic Driver Mutations Have Been Identified in Many Genes

Oncogenic Driver Mutations Can Be Identified by Comparing Cancer Genomes

Oncogenic Drivers Can Be Gain-of-Function or Loss-of-Function Mutations

Tumor Suppressor Genes and Oncogenes Often Operate in the Same Pathway

MicroRNAs Can Promote and Inhibit Tumorigenesis

Epigenetic Changes Can Contribute to Tumorigenesis

25.3 Dysregulation of Cell Growth and Developmental Pathways Initiates Tumorigenesis

Receptor Mutations Can Cause Proliferation in the Absence of External Growth Factors

Many Oncogenic Mutations Constitutively Activate Signal-Transducing Proteins

Growth Control Pathways Ultimately Regulate Initiation of the Cell Cycle

Inappropriate Production of Nuclear Transcription Factors Can Induce Transformation

Aberrations in Signaling Pathways That Control Development Are Associated with Many Cancers

Experimental Reconstruction of the Multi-Hit Model for Cancer

The Succession of Oncogenic Mutations Can Be Traced in Colon Cancers

Cancer Development Can Be Studied in Animal Models

Molecular Cell Biology Is Changing How Cancer Is Diagnosed and Treated

25.4 Evasion of Programmed Cell Death and Immune Surveillance Processes

Oncogenic Driver Mutations Enable Cancer Cells to Evade Apoptosis

p53 Can Activate Either the DNA Damage Checkpoint or Apoptosis in Response to DNA Damage

The Immune System Is a Second Line of Defense Against Cancer Formation

The Tumor Microenvironment and Immunoediting Limit the Ability of the Immune System to Detect and Kill Established Tumors

Activation of the Immune System Presents a Major Opening for Cancer Therapy

CHAPTER 1

Evolution: Molecules, Genes, Cells, and Organisms

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

Tardigrades are tiny 0.05-mm-long invertebrates that have evolved to survive exposures to extreme conditions that kill other life forms; they are the only metazoan organisms known to survive exposure to the deadly combination of low pressure and intense radiation in outer space.

[Schokraie E., Warnken U., Hotz-Wagenblatt A., Grohme M. A., Hengherr S., et al. 2012. Comparative proteome analysis of *Milnesium tardigradum* in early embryonic state *versus* adults in active and anhydrobiotic state. *PLoS ONE* **7**(9): e45682. https://doi.org./10.1371/journal.pone.0045682]

Biology is a science fundamentally different from physics or chemistry, which deal with unchanging properties of matter that can be described by mathematical equations. Biological systems, of course, follow the rules of chemistry and physics, but biology is a historical science, as the forms and structures of the living world today are the results of billions of years of evolution. Through evolution, all organisms both living and extinct are related in an

evolutionary family tree extending from primitive single-celled organisms that lived in the distant past to the diverse plants, animals, and microorganisms of the present era (Figure 1-1, Table 1-1). The great insight of Charles Darwin was the principle of natural selection: organisms vary randomly and compete within their environment for resources. Only those that survive and reproduce are able to pass down their genetic traits (Figure 1-2).

FIGURE 1-1 All living organisms descended from a common ancestral cell. All organisms, from simple bacteria to complex mammals, probably evolved from a common single-celled ancestor. This evolutionary tree depicts the relationships among the three major lineages of organisms. The structure of the tree was initially ascertained from morphological criteria: creatures that look alike were put close together. More recently, the sequences of DNA and proteins found in organisms have provided more information-rich criteria for assigning relationships. The greater the similarities in these macromolecular sequences, the more closely related organisms are thought to be. The trees based on morphological comparisons and the fossil record generally agree well with those based on molecular data. This

evolutionary tree has branches. Organisms like bacteria exchange pieces of their DNA genome with one another, and mitochondria and chloroplasts are thought to derive from primitive bacteria that took up residence inside the organisms that gave rise to present eukaryotes.

[Data from J. R. Brown, 2005, "Universal Tree of Life," in *Encyclopedia of Life Sciences*, Wiley InterScience (online).]

TABLE 1-1 • Timeline for Evolution of Life on Earth, as Determined from the Fossil Record and from Recent DNA Sequence Analyses

4600 million years ago	The planet Earth forms from material revolving around the young sun.
$\sim$3500 million years ago	Cells resembling prokaryotes appear. These first organisms are chemoautotrophs: they use carbon dioxide as a carbon source and oxidize inorganic materials to extract energy.
3000 million years ago	Photosynthesizing cyanobacteria evolve; they use water as a reducing agent, thereby producing oxygen as a waste product.
1850 million years ago	Unicellular eukaryotic cells appear.
1200 million years ago	Simple multicellular organisms evolve, mostly consisting of cell colonies of limited complexity.
580–500 million years ago	Most modern phyla of animals begin to appear in the fossil record during the Cambrian explosion.

535 million years ago	Major diversification of living things in the oceans: chordates, arthropods (e.g., trilobites, crustaceans), echinoderms, mollusks, brachiopods, foraminifers, radiolarians, etc.
485 million years ago	First vertebrates with true bones (jawless fishes) evolve.
434 million years ago	First primitive plants arise on land.
225 million years ago	Earliest dinosaurs (prosauropods) and teleost fishes appear.
220 million years ago	Gymnosperm forests dominate the land; herbivores grow to huge sizes.
215 million years ago	First mammals evolve.
65.5 million years ago	The Cretaceous-Tertiary extinction event eradicates about half of all animal species, including all of the dinosaurs.
6.5 million years ago	First hominids evolve.
~ 2 million years ago	First members of the genus *Homo* appear in the fossil record.

~450 thousand years ago	Neanderthals appear.
~300 thousand years ago	Anatomically modern humans appear in Africa.
~40 thousand years ago	Extinction of Neanderthals.

FIGURE 1-2 The first evolutionary tree in Charles Darwin's notebook. One year after his epic voyage on HMS *Beagle*, Darwin had already begun formulating his concept of natural selection, which would be published in his *On the Origin of Species* (1859). Shown here is page 36 of his 1837 "B" notebook on *Transmutation of Species;* he wrote "I think" above his first evolutionary tree. In *On the Origin of Species* he describes in greater detail the evolutionary history of organisms both living and extinct and includes a more elaborate hypothetical evolutionary tree.

[Page 36 of Charles Darwin's 1837 "B" notebook on Transmutation of Species.]

At first glance, the biological universe does appear amazingly diverse — from tiny ferns to tall fir trees, from single-celled bacteria and protozoans visible only under a microscope to multicellular animals of all kinds. The discovery that all living organisms are made up of cells was one of the most remarkable discoveries in biology. Indeed, cells come in an astonishing variety of sizes and shapes (Figure 1-3). Some move rapidly and have fast-changing structures, as we can see in movies of amoebae and rotifers. Others

are largely stationary and structurally stable. Oxygen kills some cells but is an absolute requirement for others. Most cells in multicellular organisms are intimately involved with other cells. Although some unicellular organisms live in isolation (Figure 1-3a), others form colonies or live in close association with other types of organisms (Figure 1-3b, d), such as the bacteria that help plants extract nitrogen from the air or the bacteria that live in our intestines and help us digest food.

FIGURE 1-3 Cells come in an astounding assortment of shapes and sizes. Some of the morphological variety of cells is illustrated in these photographs. In addition to morphology, cells differ in their ability to move, internal organization (prokaryotic versus eukaryotic cells), and metabolic activities. (a) Eubacteria: *Lactococcus lactis*, which are used to produce cheese such as Roquefort, Brie, and Camembert. Note the dividing cells. (b) A mass of archaeans (*Methanosarcina*) that produce their energy by converting carbon dioxide and hydrogen gas to methane. Some species that live in the rumens of cattle give rise to

>150 liters of methane gas each day. (c) Human blood cells, shown in false color. The red cells are oxygen-bearing erythrocytes, the white cells (leukocytes) are part of the immune system and fight infection, and the green false-colored cell fragments are platelets that plug wounds and contain substances to initiate blood clotting. (d) A colonial single-celled green alga, *Volvox aureus*. The surfaces of the large spheres contain thousands of individual cells, visible as blue or green dots. The yellow masses inside are daughter colonies, each made up of many cells. (e) A single Purkinje neuron of the cerebellum, which can form more than a hundred thousand connections with other cells through its branched network of dendrites. The cell was made visible by introduction of a gene-encoding green fluorescent protein; the cell body with its nucleus is the bulb at the upper right. (f) Plant cells in vascular plants are fixed firmly in place, supported by a rigid cellulose skeleton. Spaces between the cells are joined into tubes for transport of water and food.

Yet the bewildering array of outward biological forms overlies a powerful uniformity: thanks to our common ancestry, all biological systems are composed of cells containing the same types of chemical molecules and employing similar principles of organization and function at the cellular level. Although the basic kinds of biological molecules have been conserved during the billions of years of evolution, the patterns in which they are assembled to form functioning cells and organisms have undergone considerable change.

We now know that **genes**, which chemically are composed of **deoxyribonucleic acid (DNA)**, ultimately define biological structure and maintain the integration of cellular function. Many genes are copied into **messenger RNA (mRNA)** that in turn directs the synthesis of specific **proteins**, the primary molecules that make up cell structures and carry out virtually all cellular activities.

Alterations in the structure and organization of genes, or **mutations**, provide the random variation that can alter biological structure and function. While the vast majority of random mutations have no observable effect on a gene's or protein's function, many are deleterious, and only a few confer an evolutionary advantage on the organism. In all organisms, mutations in DNA are constantly occurring, allowing over time the small alterations in cellular structures and functions that may prove to be advantageous. Entirely new cellular structures are rarely created; more often, existing cellular structures undergo changes that better adapt the organism to new circumstances. Slight changes in a protein can cause important changes in its function or abolish its function entirely.

For instance, in a particular organism, one gene may randomly become duplicated, after which one copy of the gene and its encoded protein retain their original function while, over time, the second copy of the gene mutates such that its protein takes on a slightly different or even a totally new function. During the evolution of some organisms, the entire genome became duplicated, allowing the second copies of many genes to undergo mutations and acquire new functions. The cellular organization of organisms plays a fundamental role in this process because it allows these changes to come about by small alterations in previously evolved cells, giving them new abilities. The result is that closely related organisms have very similar genes and proteins as well as similar cellular and tissue organizations.

Multicellular organisms, including the human body, consist of such closely interrelated elements that no single element can be fully appreciated in isolation from the others. Organisms contain organs, organs are composed of tissues, tissues consist of cells, and cells are formed from molecules (Figure 1-4). The unity of living systems is coordinated by many levels of interrelationship: molecules carry messages from organ to organ and cell to cell, and tissues are delineated and integrated with other tissues by molecules secreted by cells. Generally all the levels into which we fragment biological systems interconnect.

FIGURE 1-4 Living systems such as the human body consist of closely interrelated elements. (a) The surface of the hand is covered by a living organ, skin, that is composed of several layers of tissue. (b) An outer covering of hard, dead skin cells protects the body from injury, infection, and dehydration. This layer is constantly renewed by living epidermal cells, which also give rise to hair and fur in animals. Deeper layers of muscle and connective tissue give skin its tone and firmness. (c) Tissues are formed through subcellular adhesion structures (desmosomes and hemidesmosomes) that join cells to one another and to an underlying layer of supporting fibers. (d) At the heart of cell-cell adhesion are its structural components: phospholipid molecules that make up the cell-surface membrane, and large protein molecules. Protein molecules that traverse the cell membrane often form strong bonds with internal and external fibers made of multiple proteins.

To learn about biological systems, however, we must examine one small portion of a living system at a time. The biology of cells is a logical starting point because an organism can be viewed as consisting of interacting cells, which are the closest thing to autonomous biological units that exist. The last common ancestor of all life on Earth was a single cell (see Figure 1-1), and at the cellular level all life is remarkably similar. All cells use the same molecular building blocks; similar methods for the storage, maintenance, and expression of genetic information; and similar processes of energy metabolism, molecular transport, signaling, development, and structure.

In this chapter, we introduce the common features of cells. We begin with a brief discussion of the principal small molecules and macromolecules found in biological systems. Next we discuss the fundamental aspects of cell structure and function that are

conserved in present-day organisms, focusing first on **prokaryotic organisms** — single-celled organisms without a nucleus — and their uses in studying the basic molecules of life. Then we discuss the structure and function of **eukaryotic cells** — cells with a defined nucleus — focusing on their many organelles. This discussion is followed by a section describing the use of unicellular eukaryotic organisms in investigations of basic aspects of molecular and cellular biology, focusing on yeasts and the ability to generate and analyze mutations in genes that are essential for life. We also discuss the parasite that causes malaria, focusing on the several dramatic transformations this cell undergoes within its human and mosquito hosts.

We then turn to the structure and function of metazoans — multicellular animals — focusing on cell–cell interactions that allow tissues and organs to form. We now have the complete sequences of the genomes of many metazoans, as well as that of several thousand prokaryotic organisms and single-celled eukaryotes; these sequences have provided considerable insight into the evolution of genes and organisms. We discuss how this sequence data has led to the development of many new data-driven and computer-based techniques — the fields of *genomics* and *bioinformatics* — that have greatly informed our knowledge about biology. Analysis of the complete sequences of thousands of human DNAs has led, for example, to identification of mutations in many genes that cause human diseases. Analysis of ancient DNA samples has led to an

understanding of the relationships between modern humans and extinct Neanderthals and the finding that many humans today have up to 2 percent of their DNA genome derived from Neanderthals as a result of matings thousands of years ago (Figure 1-5). Such DNA studies have also elucidated the migratory pathways taken by ancient humans in and from Africa to their present locations. Analysis of messenger RNAs present in individual human cells has led to the discovery of totally new types of cells in the human body. Continuing advances in genomics and bioinformatics, along with developments in artificial intelligence and machine learning over the coming years will certainly illuminate many other aspects of human biology and disease.

FIGURE 1-5 Approximate proportions of Neanderthal DNA found in present day humans. Humans bred with Neanderthals in the distant past, most likely in present-day Europe, and up to 2 percent of the DNA in present-day humans has a sequence derived from Neanderthal DNA. Plotted in this graph is the amount of Neanderthal DNA in humans in various locations, relative to the maximum observed of 2 percent. The entire Neanderthal genome was first sequenced from several $\sim 40{,}000$-year-old bones found in a cave in Croatia; clearly Neanderthals mated with forerunners of modern humans in Eurasia, and we see different segments of Neanderthal DNA remaining in different modern non-African people. Neanderthal DNA is nearly absent from indigenous people living in South Africa, presumably because the great majority of their ancestors never encountered Neanderthals.

[Data from: "Map" by Oliver Uberti, copyright © 2018 by David Reich & Eugenie Reich; from *Who We Are and How We Got Here: Ancient DNA and the New Science of the Human Past* by David Reich, Pantheon Books.]

In the final section of this chapter we introduce several widely studied metazoans — the fruit fly *Drosophila melanogaster*, the roundworm *Caenorhabditis elegans*, planaria, and the zebrafish *Brachydanio rerio* — that have been especially useful in uncovering the conserved roles of many genes in metazoan development and function. We show how the accumulating amount of genetic data is and will continue to be analyzed to refine the evolutionary relationships among organisms as well as our understanding of human development, function, and disease. Indeed, biologists use evolution as a research tool: if a gene and its protein have been conserved in all metazoans but are not found in unicellular organisms, the protein probably has an important function in all metazoans and thus can be studied in whatever metazoan organism is most suitable for the investigation. Because the structure and function of many types of metazoan cells are also conserved, we now understand the structure and function of many cell types in considerable detail, including muscle and liver cells and the sheets of epithelial cells that line the intestine and form our skin. But many other cells — especially the multiple types that form our nervous and immune systems — still retain mysteries we need to solve; much important cell biological experimentation is needed on these and other cell systems and organs that form our bodies.

1.1 The Molecules of Life

While large polymers are the focus of molecular and cellular biology, small molecules are the stage on which all cellular processes are set. Water, inorganic ions, and a wide array of relatively small organic molecules (Figure 1-6) account for 75 to 80 percent of living matter by weight, and water accounts for about 75 percent of a cell's volume. These small molecules serve as substrates for many of the chemical reactions that take place inside the cell, including the reactions of energy metabolism and cell signaling. Cells acquire these small molecules in different ways. Ions, water, and many small organic molecules are imported into the cell (see Chapter 11); other small molecules are synthesized within the cell, often by a series of chemical reactions (see Chapter 12).

FIGURE 1-6 Some of the many small molecules found in cells. Only the L-forms of amino acids, such as serine depicted here, are found in cells and incorporated into proteins, not their D-mirror images. Only the D-form of glucose, not its L-mirror image, is found in nature and can be metabolized by cells to carbon dioxide and water.

Even in the structures of many small molecules, such as sugars, vitamins, and amino acids, we see the footprint of evolution. For example, all amino acids except glycine have an asymmetric carbon atom, yet only the L-stereoisomer, never the D-stereoisomer, is incorporated into proteins. Similarly, only the D-stereoisomer of glucose is found in organisms, never the mirror-image L-stereoisomer (see Figure 1-6). At an early stage of biological evolution, our common cellular ancestor evolved the ability to

catalyze chemical reactions that act on one stereoisomer instead of the other. How these selections happened is unknown, but now these choices are locked in place.

The small molecules in cells have a variety of functions, For example, the universally conserved small molecule **adenosine triphosphate (ATP)** stores readily available chemical energy in two of its chemical bonds (Figure 1-7). When one of these energy-rich bonds in ATP is broken, forming **ADP (adenosine diphosphate)** and inorganic phosphate, HPO_4^{2-}, often abbreviated P_i, the released energy can be harnessed to power energy-requiring processes such as muscle contraction or protein biosynthesis. To obtain energy for making ATP, many types of cells break down food molecules. For instance, when sugar is degraded to carbon dioxide and water, the energy stored in the sugar molecule's chemical bonds is released, and much of it can be captured in the energy-rich bonds in ATP (see Chapter 12). Bacterial, plant, and animal cells can all make ATP by this process. In addition, plants and a few other organisms can harvest energy from sunlight to form ATP in **photosynthesis**. Some prokaryotes that live in extreme environments produce ATP by catalyzing reactions with reduced compounds like hydrogen sulfide (H_2S).

FIGURE 1-7 Adenosine triphosphate (ATP) is the most common molecule used by cells to capture, store, and transfer energy. ATP is formed from adenosine diphosphate (ADP) and inorganic phosphate (P_i) by photosynthesis in plants and photosynthetic algae and by the breakdown of sugars and fats in most cells. The energy released by the splitting (hydrolysis) of P_i from ATP drives many cellular processes.

Other small molecules (e.g., hormones such as adrenaline and histamine) act as signals that direct the activities of cells (see Chapters 15 and 16), and neurons (nerve cells) communicate with one another by releasing and sensing certain small signaling molecules such as serotonin (see Chapter 23). The powerful physiological effects of a frightening event, for example, come from the instantaneous flooding of the body with the small-molecule

hormone adrenaline, which mobilizes the fight-or-flight response (see Chapter 15).

Certain small molecules (**monomers**) can be joined to form **polymers** (also called **macromolecules**) through repetition of a single type of covalent chemical-linkage reaction. Cells produce three types of large macromolecules: polysaccharides, proteins, and nucleic acids. Sugars, for example, are the monomers used to form polysaccharides. Different polymers of D-glucose form cellulose, an important component of plant cell walls (see Chapter 20), and glycogen, a storage form of glucose found in liver and muscle (see Chapter 15). The cell is careful to provide the appropriate mix of small molecules needed as precursors for synthesis of macromolecules.

Proteins Give Cells Structure and Perform Most Cellular Tasks

Proteins, the workhorses of the cell, are the most abundant and functionally versatile of the cellular macromolecules. Cells string together 20 different **amino acids** (see Figure 2-14) in linear chains, each with a defined sequence, to form proteins, which commonly range in length from 100 to 1000 amino acids. During or just after its polymerization, a linear chain of amino acids folds into a complex shape, conferring a distinctive three-dimensional structure and

function on the protein (Figure 1-8). Humans obtain amino acids either by synthesizing them from other molecules or by breaking down proteins that we eat.

FIGURE 1-8 Models of some representative proteins drawn to a common scale and compared with a small portion of a lipid bilayer, a double-stranded DNA molecule, and a single-stranded RNA molecule. Each protein has a defined three-dimensional shape held together by numerous covalent and noncovalent chemical bonds. The illustrated proteins include enzymes (glutamine synthetase and adenylate kinase), an antibody (immunoglobulin), a hormone (insulin), and the oxygen carrier (hemoglobin) in red blood cells.

[Glutamine synthetase data from H. S. Gill and D. Eisenberg, 2001, *Biochemistry* **40**:1903–1912, PDB ID 1fpy. Insulin data from E. N. Baker et al., 1988, *Phil. Trans. R. Soc. Lond. B Biol. Sci.* **319**:369–456, PDB ID 4ins. Hemoglobin data from G. Fermi et al., 1984, *J. Mol. Biol.* **175**:159–174, PDB ID 2hhb. Immunoglobulin data from L. J. Harris et al., 1998, *J. Mol. Biol.* **275**:861–872, PDB ID 1igy. Adenylate kinase data from G. Bunkoczi et al., PDB ID 2c9y.]

Proteins have a variety of functions in the cell. Many proteins are **enzymes**, which accelerate (catalyze) chemical reactions involving

small molecules or macromolecules (see Chapter 3). Certain proteins catalyze steps in the synthesis of all proteins; others catalyze synthesis of macromolecules such as DNA and RNA (see Chapter 5). Other proteins form long fibers that serve as structural components of a cell, for example, by forming an internal skeleton termed the *cytoskeleton*. Other proteins associated with the cytoskeleton power the movement of subcellular structures such as chromosomes, and even of whole cells, by using energy stored in the chemical bonds of ATP (see Chapters 17 and 18). Still other proteins bind adjacent cells together or form parts of the extracellular matrix (see Figure 1-4). Proteins can be sensors that change shape as temperature, ion concentrations, or other properties of the cell change. Many proteins that are embedded in the cell-surface (plasma) membrane import and export a variety of small molecules and ions (see Chapter 11). Some proteins, such as insulin, are hormones; others are hormone receptors that bind their target protein or small molecule and then generate a signal that regulates a specific aspect of cell function (see Chapters 15 and 16). Other important classes of proteins bind to specific segments of DNA, turning genes on or off (see Chapter 8). In fact, much of molecular cell biology consists of studying the function of specific proteins in specific cell types.

Nucleic Acids Carry Coded Information for Making Proteins at the Right Time

and Place

The macromolecule that garners the most public attention is deoxyribonucleic acid (DNA), whose functional properties make it the cell's master molecule. The three-dimensional structure of DNA was first proposed by James D. Watson and Francis H. C. Crick in 1953 based on the x-ray crystal analysis of DNA by Rosalind Franklin. The DNA molecule consists of two long helical strands that are coiled around a common axis to form a **double helix** (Figure 1-9). The double-helical structure of DNA, one of nature's most magnificent constructions, is critical to the phenomenon of **heredity**, the transfer of genetically determined characteristics from one generation to the next.

FIGURE 1-9 DNA consists of two complementary strands wound around each other to form a double helix. The double helix is stabilized by weak hydrogen bonds between the A and T bases and between the C and G bases as well as by interactions between the stacked bases. During replication, the two strands are unwound and used as templates to produce complementary strands. The outcome is two identical copies of the original double helix, each containing one of the original strands and one new daughter (complementary) strand.

DNA strands are composed of monomers called **nucleotides**; these monomers are often referred to as *bases* because they contain cyclic organic bases (see Chapter 5). Four different nucleotides, abbreviated A, T, C, and G, are joined to form a DNA strand, with the base parts projecting inward from the backbone of the strand. Two strands bind together via hydrogen bonding between the bases in the strands and twist to form a double helix. Each DNA double helix has a simple construction: wherever one strand has an A, the other strand has a T, and each C is matched with a G (see Figure 1-9). This **complementary** matching of the two strands is so strong that if complementary strands are separated under the right salt concentration and temperature conditions, they will spontaneously zip back together. This property is critical for DNA replication and inheritance, as we will learn in Chapter 5, and also underlies many of the techniques for studying DNA molecules that are detailed in Chapter 6.

The genetic information carried by DNA resides in its *sequence*, the linear order of nucleotides along a strand. Specific segments of DNA, termed *genes*, carry instructions for making specific proteins. Most bacteria have a few thousand protein-coding genes; yeasts and other unicellular eukaryotes have about 5000. Humans and other metazoans have between 13,000 and 23,000, while many plants have more (Table 1-2).

TABLE 1-2 • Genome Sizes of Organisms Used in Molecular Cell Biology Research That Have Been Completely Sequenced

	Base Pairs (Millions)	Approximate Number of Encoded Proteins[i]	Chromosomes[ii]	Reference
Eubacteria				
Mycoplasma genitalium	0.58	500	1	a
Helicobacter pylori	1.67	1,500	1	a
Haemophilus influenzae	1.83	1,600	1	a
Escherichia coli	4.64	4,100	1	a
Bacillus subtilis	4.22	4,200	1	a
Archaea				
Methanococcus jannaschii	1.74	1,800	1	a
Sulfolobus solfataricus	2.99	3,000	1	a
Single-Celled Eukaryotes				
Saccharomyces cerevisiae	12.16	6,700	16	b
Chlamydomonas reinhardtii	120.4	14,400	17	b

Plasmodium falciparum	23.26	5,400	14	b
Multicellular Eukaryotes (Metazoans)				
Drosophila melanogaster	168.74	13,900	6	b
Caenorhabditis elegans	100.29	20,500	6	b
Schmidtea mediterranea (planarian)	480	$>20,000$[iii]	4	c
Danio rerio (zebrafish)	1412.46	26,500	25	b
Gallus gallus (chicken)	1072.54	15,500	33	b
Mus musculus (mouse)	3480.96	23,100	21	b
Homo sapiens (human)	3326.74	20,800	24	b
Arabidopsis thaliana	135.67	27,400	5	b

[i]Numbers of encoded proteins are current estimates rounded to the nearest 100 based on genome DNA sequences. They will most likely change slightly in Eubacteria and Archaea because of the inclusion of newly discovered genes that code for very small proteins, and modestly in eukaryotes because of newly discovered small genes and because of pseudogenes that are not expressed.

[ii]Only nuclear chromosomes are counted in eukaryotes, including distinct sex chromosomes in metazoans.

[iii]Predicted value.

As we discuss later in this chapter, many of the genes in bacteria specify the sequences of proteins that catalyze reactions that occur universally, such as the metabolism of glucose and the synthesis of nucleic acids and proteins. These genes, and the proteins encoded by them, are conserved throughout all living organisms, and thus studies on the functions of the genes and proteins in bacterial cells have yielded profound insights into basic life processes. Similarly, many genes in unicellular eukaryotes, such as yeasts, encode proteins that are conserved throughout all eukaryotes but are not found in prokaryotes; we will see how yeasts have been used in studies of processes such as cell division that have yielded profound insights into human diseases such as cancer.

How is information stored in the DNA sequences converted into proteins? Cells use two processes in series (Figure 1-10). In the first process, called **transcription**, the protein-coding region of a gene is copied into a single-stranded **ribonucleic acid (RNA)** whose sequence is the same as one of the two strands of the double-stranded DNA. A large enzyme, **RNA polymerase**, catalyzes the

linkage of nucleotides into an RNA chain using DNA as a template. In eukaryotic cells, the initial RNA product is processed into a smaller messenger RNA molecule, which moves out of the nucleus to the **cytoplasm**, the region of the cell outside of the nucleus. Here the **ribosome**, an enormously complex molecular machine composed of both RNA and proteins, carries out the second process, called **translation**. During translation, the ribosome assembles and links together amino acids in the precise order dictated by the mRNA sequence according to the nearly universal **genetic code**. We examine the cell components that carry out transcription and translation in detail in Chapter 5.

FIGURE 1-10 In eukaryotic cells the information encoded in DNA is converted into the amino acid sequences of proteins by a multistep process. Step 1 : Transcription factors and other proteins bind to the regulatory regions of the specific genes they control to

activate those genes. Step 2: RNA polymerase begins transcription of an activated gene at a specific location, the start site. The polymerase moves along the DNA, linking nucleotides into a single-stranded pre-mRNA transcript using one of the DNA strands as a template. Step 3: The transcript, whose nucleotide sequence is identical to that of the nontemplate strand, is processed to remove noncoding intron sequences. Step 4: The mature mRNA moves to the cytoplasm, where it is bound by ribosomes that read its sequence and assemble a protein by chemically linking amino acids one at a time into a linear chain.

In addition to its role in transferring information from nucleus to cytoplasm, RNA can serve as a framework for building a molecular machine. The ribosome, for example, is built of four RNA chains that bind to more than 50 proteins to make a remarkably precise and efficient mRNA reader and protein synthesizer. While most chemical reactions in cells are catalyzed by proteins, a few, such as the formation by ribosomes of the peptide bonds that connect amino acids in proteins, are catalyzed by RNA molecules.

Well before the entire human genome was sequenced, it was apparent that only about 10 percent of human DNA consists of protein-coding genes, and for many years the remaining 90 percent was considered "junk DNA"! In recent years, we've learned that much of the so-called junk DNA is actually copied into thousands of RNA molecules that, though they do not encode proteins, serve equally important purposes in the cell (see Chapter 9). At present, however, we know the function of only a very few of these abundant noncoding RNAs.

Like enzymes, certain RNA molecules, termed **ribozymes**, catalyze chemical reactions, as exemplified by the RNA inside a ribosome. Many scientists support the *RNA world* hypothesis, which proposes that RNA molecules that could replicate themselves were the precursors of current life forms; billions of years ago, the RNA world gradually evolved into the DNA, RNA, and protein world of today's organisms.

All organisms must control when and where their genes are transcribed. Nearly all the cells in our bodies contain the full set of human genes, but in each cell type only some of these genes are active, or turned on, and used to make proteins. For instance, liver cells produce some proteins that are not produced by muscle cells, and vice versa. Moreover, many cells respond to external signals or changes in external conditions by turning specific genes on or off, thereby adapting their repertoire of proteins to meet current needs. Commonly, protein-coding genes contain two parts: the coding region specifies the amino acid sequence of a protein, and the regulatory region binds specific proteins called **transcription factors**, which act as switches, either activating or repressing transcription of particular genes, as discussed in Chapter 8. By this means, the regulatory region controls when and in which cells the gene's encoded protein is made.

Phospholipids Are the Conserved Building Blocks of All Cellular Membranes

Life depends on cells being enclosed by a surface membrane that forms the interface of a cell with its environment. In eukaryotes, membranes also surround all of the internal compartments, termed *organelles*. Small molecules called *phospholipids* spontaneously pack together in such a way that they form the basic structure of these membrane sheets. Each of these bipartite molecules has a "water-loving" (hydrophilic) "head" and a "water-hating" (hydrophobic) "tail" composed of fatty acid chains. Cellular membranes are composed primarily of a bilayer (two layers) of phospholipid molecules. The two phospholipid layers of a membrane are oriented with all the hydrophilic heads directed toward the inner or outer surfaces of the membrane and the hydrophobic tails buried within its interior (Figure 1-11). Smaller amounts of other lipids, such as cholesterol, are inserted into this phospholipid framework. Cellular membranes are extremely thin relative to the size of a cell. If you magnify a bacterium or yeast cell about 10,000 times to the size of a soccer ball, the plasma membrane is about as thick as a sheet of paper!

FIGURE 1-11 The watery interior of cells is surrounded by the plasma membrane, a two-layered shell of phospholipids. The phospholipid molecules are oriented with their hydrophobic fatty acyl chains (black squiggly lines) facing inward and their hydrophilic head groups (spheres) facing outward. Thus both sides of the membrane are lined by head groups, mainly charged phosphates, adjacent to the watery spaces inside and outside the cell. All biological membranes have the same basic phospholipid bilayer structure. Cholesterol (red) and various proteins are embedded in the bilayer. The interior space is vastly larger relative to the volume of the plasma membrane than is depicted here.

Phospholipid membranes are impermeable to water, all ions, and virtually all hydrophilic small molecules. Thus each membrane in each cell also contains groups of proteins that allow specific ions and small molecules to cross. Other membrane proteins serve to attach the cell to other cells or to polymers that surround it (see Figure 1-4); still others give the cell its shape or allow its shape to change. We will learn more about membranes and how molecules cross them in Chapters 10 and 11.

New cells are always derived from parental cells by cell division. We've seen that the two strands of the parental DNA are templates for the synthesis of new DNA molecules such that each daughter DNA molecule has the same sequence as the parental one. In parallel, new membranes are made by incorporation of phospholipids and proteins into existing membranes in the parental cell and divided between daughter cells by fission. Thus membrane synthesis, like DNA synthesis, is templated by a parental structure.

Quality Control of All Cellular Macromolecules Is Essential for Life

All cells are constantly bombarded by potentially hazardous chemicals and radiation that can damage the macromolecules within, and cells expend a significant amount of their energy to ensure that damaged molecules — especially DNA — are repaired or degraded. Proteins function only when they are folded into their proper three-dimensional structure (see Figure 1-8). Proteins that fail to fold, or become unfolded as a result of stresses such as an elevated temperature, are usually rapidly degraded by enzymes within the cell, releasing their constituent amino acids, which are reused for making new proteins. Occasionally, though, misfolded proteins aggregate together inside the cell, causing damage to the cell. As discussed in Chapter 3, such protein aggregates that form

over time in brain nerve cells are thought to be the cause of Alzheimer's and other neurodegenerative diseases.

Ultraviolet and gamma radiation, as well as many chemicals, can damage DNA, causing changes in the normal DNA sequence. Such mutations can cause errors in DNA replication and lead to inability of that sequence to direct the synthesis of the correct protein. Cells have several mechanisms, discussed in Chapter 5, to repair such damage to DNA, converting the mutation back to the normal sequence. Occasionally mutations are not repaired and cause death of the cell. Alternatively, unrepaired mutations can cause proteins to be made in the wrong cell or at the wrong time and lead to uncontrolled growth of the cell. Chapter 25 details how many types of mutations that occur over an individual's life cause cancer.

1.2 Prokaryotic Cell Structure and Function

The biological universe consists of two types of cells: prokaryotic and eukaryotic. Prokaryotic cells such as bacteria consist of a single closed compartment that is surrounded by a plasma membrane, lack a defined nucleus, and have a relatively simple internal organization (Figure 1-12). Eukaryotic cells contain a defined membrane-bounded nucleus and extensive internal membranes that enclose the organelles (Figure 1-13).

FIGURE 1-12 Prokaryotic cells have a relatively simple structure. (a) Electron micrograph of a thin section of *Escherichia coli*, a common intestinal bacterium. The nucleoid, consisting of the bacterial DNA, is not enclosed within a membrane. *E. coli* and other gram-negative bacteria are surrounded by two membranes separated by the periplasmic space. The thin cell wall is adjacent to the inner membrane. (b) This artist's drawing shows the nucleoid (blue) and a magnification of the layers that surround the cytoplasm in a gram-negative bacterium. Most of the cell is composed of water, proteins, ions, and other molecules that are too small to be depicted at the scale of this drawing.

1. Plasma membrane controls movement of molecules in and out of the cell and functions in cell-cell signaling and cell adhesion.
2. Mitochondria, which are surrounded by a double membrane, generate ATP by oxidation of glucose and fatty acids.
3. Lysosomes, which have an acidic lumen, degrade material internalized by the cell and worn-out cellular membranes and organelles.
4. Nuclear envelope, a double membrane, encloses the contents of the nucleus; the outer nuclear membrane is continuous with the rough ER.
5. Nucleolus is a nuclear subcompartment where most of the cell´s rRNA is synthesized.
6. Nucleus is filled with chromatin composed of DNA and proteins; site of mRNA and tRNA synthesis.
7. Smooth endoplasmic reticulum (ER) contains enzymes that synthesize lipids and detoxify certain hydrophobic molecules.
8. Rough endoplasmic reticulum (ER) functions in the synthesis, processing, and sorting of secreted proteins, lysosomal proteins, and certain membrane proteins.
9. Golgi complex processes and sorts secreted proteins, lysosomal proteins, and membrane proteins synthesized on the rough ER.
10. Secretory vesicles store secreted proteins and fuse with the plasma membrane to release their contents.
11. Peroxisomes contain enzymes that break down fatty acids into smaller molecules used for biosynthesis and also detoxify certain molecules.
12. Cytoskeletal fibers form networks and bundles that support cellular membranes, help organize organelles, and participate in cell movement.
13. Microvilli increase surface area for absorption of nutrients from surrounding medium.
14. Cell wall, composed largely of cellulose, helps maintain the cell´s shape and provides protection against mechanical stress.
15. Vacuole stores water, ions, and nutrients, degrades macromolecules, and functions in cell elongation during growth.
16. Chloroplasts, which carry out photosynthesis, are surrounded by a double membrane and contain a network of internal membrane-bounded sacs.
17. Plasmodesmata are tubelike cell junctions that span the cell wall and connect the cytoplasms of adjacent plant cells.

FIGURE 1-13 Subcellular organization of eukaryotic cells. (a) Schematic overview of a typical animal cell (*top*) and plant cell (*bottom*) and their major substructures. Not every cell type will contain all the organelles, granules, and fibrous structures shown here, and other substructures can be present in some cell types. Cells also differ considerably in shape and

in the prominence of various organelles and substructures. (b) Electron micrograph of a plasma cell, a type of white blood cell that secretes antibodies, showing some of the larger organelles. Not all of the organelles are labeled.

Prokaryotes Comprise Two Kingdoms: Archaea and Eubacteria

In recent years, detailed analysis of DNA sequences from a variety of prokaryotic organisms has revealed two distinct kingdoms: the Eubacteria, often simply called "bacteria," and the *Archaea* (see Figure 1-1). Eubacteria are single-celled organisms; they include the photosynthetic cyanobacteria, or "blue-green algae." Figure 1-12 illustrates the general structure of a typical eubacterial cell; archaeal cells have a similar structure. Bacterial cells are commonly 1–2 μm in size and consist of a single closed compartment containing the cytoplasm and bounded by the plasma membrane. The genome is composed of a single circular, double-stranded DNA molecule; many prokaryotes contain additional small circular DNA molecules called *plasmids*. Although bacterial cells do not have a defined nucleus, the DNA is extensively folded into the central region of the cell, called the *nucleoid*. Many proteins are precisely localized within the cytosol or nucleoid or in the plasma membrane or cell wall, indicating the presence of an elaborate structural and functional organization.

Most ribosomes are found in the cytoplasm. Unlike mRNAs in eukaryotes (see Figure 1-10), bacterial mRNAs undergo limited if any processing. Because there is no membrane barrier between bacterial DNA and cytoplasm, ribosomes are able to bind to an mRNA as soon as part of it has been synthesized by RNA polymerase; thus in prokaryotes, transcription and translation occur contemporaneously.

Bacterial cells possess a cell wall, which lies adjacent to the external side of the plasma membrane. The cell wall is composed of layers of peptidoglycan, a complex of proteins and oligosaccharides; it helps protect the cell and maintain its shape. Some bacteria (e.g., *E. coli*) have a thin inner cell wall and an outer membrane separated from the inner cell wall by the periplasmic space. Such bacteria are not stained by the Gram technique and thus are classified as gram-negative. Other bacteria (e.g., *Bacillus polymyxa*) that have a thicker cell wall and no outer membrane take the Gram stain and thus are classified as gram-positive.

In addition to DNA sequence distinctions that separate them from Eubacteria, Archaea have cell membranes that differ dramatically in composition from those of Eubacteria and eukaryotes. Many archaeans grow in unusual, often extreme, environments that may resemble the ancient conditions that existed when life first appeared on Earth. For instance, halophiles ("salt lovers") require high concentrations of salt to survive, and thermoacidophiles ("heat and

acid lovers") grow in hot (80 °C) sulfur springs, where a pH of less than 2 is common.

Many Bacteria Including *Escherichia coli* Are Widely Used in Biological Research

The bacterial lineage includes *Escherichia coli*, a favorite experimental organism, which in nature is common in soil and in animal intestines. *E. coli* and several other bacteria have a number of advantages as experimental organisms. They grow rapidly in a simple and inexpensive medium containing glucose and salts, in which they can synthesize all necessary amino acids, lipids, vitamins, and other essential small molecules. Like all bacteria, *E. coli* possesses elegant mechanisms for controlling gene activity that are now well understood. Over time, researchers have developed powerful systems for genetic analysis of this organism. These systems are facilitated by the small size of bacterial genomes, the ease of obtaining mutants, the availability of techniques for transferring genes into bacteria, an enormous wealth of knowledge about bacterial gene control and protein functions, and the relative simplicity of mapping genes relative to one another in the bacterial genome. In Chapter 6, we see that *E. coli* is widely used today in multiple types of recombinant DNA research.

Bacteria such as *E. coli* that grow in environments as diverse as the soil and the human gut have about 4000 genes, encoding about the same number of proteins (see Table 1-2). Certain disease-causing bacteria that only grow inside human cells, such as *Chlamydia,* have only ~1000 genes; they acquire amino acids and other nutrients from their host cells and thus have evolved to lack genes for enzymes that catalyze reactions in the synthesis of amino acids and certain lipids. Other parasitic bacteria such as *Mycoplasma* species have even fewer genes.

Many bacterial genes encoding proteins essential for DNA, RNA, and protein synthesis, and for membrane function are conserved in all organisms, and much of our knowledge of these important cellular processes was uncovered first by studies in *E. coli* and other bacteria. For example, certain *E. coli* membrane proteins that import amino acids across the plasma membrane are closely related in sequence, structure, and function to membrane proteins in mammalian brain cells that import small nerve-to-nerve signaling molecules called *neurotransmitters* (see Chapters 11 and 23).

Throughout this chapter, we will encounter eukaryotic organisms that have been chosen for study because, like *E. coli*, they are easy to grow and study. Of course, many bacteria cause serious diseases. Research on disease-causing bacteria is often focused on understanding their unique biology and on discovering antibiotics

that selectively kill them but not their human or animal hosts — for instance, drugs that block formation of parts of the cell wall.

1.3 Eukaryotic Cell Structure and Function

Eukaryotes comprise all members of the plant and animal kingdoms as well as protozoans (*proto*, "primitive"; *zoan*, "animal"), which are exclusively unicellular and include fungi and amoebae. Eukaryotic cells are commonly about 10–100 μm across, generally much larger than bacteria. A typical human fibroblast, a connective tissue cell, is about 15 μm across, with a volume and dry weight some thousands of times those of an *E. coli* cell. An amoeba, a single-celled protozoan, can have a cell diameter of approximately 0.5 mm, more than 30 times that of a fibroblast.

Eukaryotic cells, like prokaryotic cells, are surrounded by a plasma membrane. However, unlike prokaryotic cells, all eukaryotic cells (the human red blood cell is an exception) also contain extensive internal membranes that enclose specific subcellular compartments, the **organelles** (see Figure 1-13). The **cytosol**, the organelle-free part of the cytoplasm, contains water, dissolved ions, small molecules, and many types of proteins. Plant cells and most fungal cells are surrounded by a cell wall that gives the cell a rigid shape and also allows for rapid cell expansion.

All eukaryotic cells have many of the same organelles and other subcellular structures, attesting to their common evolutionary origin. Many organelles are surrounded by a single phospholipid

membrane, but the nucleus, mitochondrion, and chloroplast are enclosed by two membranes. Each organelle membrane and each space in the interior of an organelle has a unique and specific set of proteins that enable each type of organelle to have a distinct physiological function — for example, production of ATP from ADP and P_i occurs in mitochondria and chloroplasts; and many lipids, membrane proteins, and proteins to be secreted from cells are synthesized in the rough endoplasmic reticulum. Many outworn or misfolded proteins are degraded in lysosomes and their constituent amino acids recycled. Much like a factory building automobiles or computers, such compartmentalization of functions allows the cell as a unit to operate efficiently.

The membranes defining these subcellular compartments contain proteins that control their internal ionic composition so that the internal composition of each compartment generally differs from that of the surrounding cytosol as well as compartments in the other organelles. Here we describe the organelles common to all eukaryotic cells as well as several that are found only in certain types of eukaryotes. We begin with the proteins that give eukaryotic cells their shapes and organize the organelles.

The Cytoskeleton Has Many Important Functions

The cytoplasm contains an array of fibrous proteins collectively called the **cytoskeleton** (see Chapters 17 and 18). Three classes of fibers compose the cytoskeleton: **microtubules** (20 nm in diameter), built of polymers of the protein tubulin; **microfilaments** (7 nm in diameter), built of the protein actin; and **intermediate filaments** (10 nm in diameter). All of these fibers are long chains of multiple copies of one or more small protein subunits (Figure 1-14).

FIGURE 1-14 The three types of cytoskeletal filaments have characteristic distributions within mammalian cells. Three views of the same cell. A cultured fibroblast was treated with a detergent to make it permeable to large molecules and then treated with three different antibody preparations. Each antibody binds specifically to the protein monomers forming one type of filament and is chemically linked to a differently colored fluorescent dye (green, blue, or red). Visualization of the stained cell in a fluorescence microscope reveals the locations of filaments bound to a particular dye-antibody preparation. In this case, microtubules are stained blue; actin microfilaments, red; and intermediate filaments, green. All three fiber systems contribute to the shape and movements of cells.

The cytoskeleton has many crucial functions. It gives the cell strength and rigidity, thereby helping to maintain its shape; this is perhaps most obvious with neurons, in which microtubules and other fibers allow the formation of the long, slim protuberances — the axons and dendrites (see Figure 1-3e and Chapter 23) — that

emanate from the cell body and allow each neuron to carry out its specialized functions. Certain cytoskeletal fibers provide the tracks along which many organelles move, thus ensuring that they are localized to the correct place in the cytosol. Other fibers play key roles in cell motility and, in muscle cells, the ability to contract. Perhaps most important, cell division and the segregation of chromosomes and organelles into the two daughter cells could not occur without the organizational framework provided by the microtubule cytoskeleton and its associated proteins (Chapter 19).

Cilia and **flagella** are similar fingerlike extensions of the cell surface. Surrounded by the plasma membrane, they contain a bundle of microtubules that gives them their shape and, acting together with motor proteins, allows them to beat rhythmically. They propel materials across epithelial surfaces (Figure 1-15), enable sperm to swim, and push eggs through the oviduct (see Chapter 18). As detailed in Chapter 16, most vertebrate cells contain at least one cilium that plays a key role in cell-cell signaling.

FIGURE 1-15 Surface of the ciliated epithelium lining a mammalian trachea viewed in a scanning electron microscope. Beating cilia, which have a core of microtubules, propel mucus and foreign particles out of the respiratory tract, keeping the lungs and airways clear.

The Nucleus Contains the DNA Genome, Apparatuses for Synthesis of DNA and RNA, and a Fibrous Matrix

In a growing or differentiating cell, the **nucleus**, the largest organelle in animal cells, is the site of DNA replication and the synthesis of ribosomal RNA, mRNA, and a large variety of noncoding RNAs (see Chapters 5 and 8). The nucleus is surrounded

by two membranes, each one a phospholipid bilayer containing many different types of proteins (Figure 1-16). The *inner nuclear membrane* defines the nucleus itself. In most cells, the *outer nuclear membrane* is continuous with the endoplasmic reticulum, and the space between the inner and outer nuclear membranes is continuous with the lumen — the central cavity — of the endoplasmic reticulum (Figure 1-16a). The two nuclear membranes appear to come together at **nuclear pore complexes**, ringlike structures composed of specific membrane proteins embedded in the inner and outer membranes. RNAs and proteins move between the nucleus and the cytosol through these nuclear pores (red arrow in Figure 1-16a). The structure of the nuclear pores and the regulated transport of material through them are detailed in Chapters 9 and 13. Intermediate-filament proteins called **lamins** form a two-dimensional network, called the **nuclear lamina**, that adheres to the inner surface of the inner membrane, giving it shape and rigidity. The lamina breaks down early in cell division and is reassembled after the two daughter cells have separated, as we detail in Chapter 19.

FIGURE 1-16 Structure of the nucleus. (a) Schematic diagram of the structure of a typical cell nucleus and the connection of the outer nuclear membrane with the rough endoplasmic reticulum. The small black dots attached to the membrane of the rough endoplasmic reticulum are ribosomes that are synthesizing membrane and secreted proteins. The red arrow depicts the bidirectional movement of molecules between the nucleus and cytosol through the nuclear pores. For simplicity, many of the organelles in the cytoplasm (see Figure 1-13) are not shown. (b) Electron micrograph of a pancreatic acinar cell from the bat *Myotis lucifugus*. The nucleolus is a subcompartment of the nucleus and is not surrounded by a membrane; ribosomal RNA is produced in the nucleolus and ribosomes are assembled there from ribosomal RNA and ribosomal proteins. Darkly staining areas in the nucleus outside the nucleolus are regions of heterochromatin, regions of chromatin that are compact and unable to be transcribed into messenger RNA.

The total DNA in an organism is referred to as its **genome**. In prokaryotic cells, most or all of the genetic information resides in a single circular DNA molecule about a millimeter in length; this molecule lies, folded back on itself many times, in the central region of the micrometer-sized cell (see Figure 1-12 and Table 1-2). In contrast, DNA in the nuclei of eukaryotic cells is distributed among

multiple long linear structures called **chromosomes**. The length and number of chromosomes are the same in all cells of a particular species, but vary among different species (see Table 1-2). As detailed in Chapter 7, each chromosome comprises a single DNA molecule associated with numerous histones and other proteins. In a nucleus that is not dividing, the chromosomes are dispersed and are not dense enough to be observed in the light microscope.

Typical nuclei contain several subcompartments, not bound by membranes, that have specific functions. The largest, the *nucleolus*, gathers together the parts of several different chromosomes containing the genes that direct the synthesis of ribosomal RNA and is the site of assembly of the ribosomal RNAs and ribosomal proteins into ribosomes.

When nondividing cells are visualized in an electron microscope, the non-nucleolar regions of the nucleus, called the *nucleoplasm*, can be seen to have dark- and light-staining areas. The dark areas, which are often closely associated with the nuclear membrane, contain condensed, concentrated DNA that cannot be transcribed into RNA, called **heterochromatin** (see Figure 1-16b).

Chromosomes, which stain intensely with basic dyes, are visible in light and electron microscopes only during cell division, when the DNA becomes tightly compacted (Figure 1-17). Although the large genomic DNA molecule in prokaryotes is also associated with

proteins, the arrangement of DNA within a bacterial chromosome differs greatly from that within the linear chromosomes of eukaryotic cells; bacterial chromosomes are circular and are associated with different types of proteins than are eukaryotic chromosomes.

FIGURE 1-17 Individual chromosomes can be seen in cells during cell division (mitosis). (a) During the S phase of the cell cycle (see Figure 1-22) the chromosomal DNA together with its attached proteins (not shown) is duplicated, and the daughter *sister chromatids*, each with a complete copy of the chromosomal DNA, remain attached at the centromere. (b) During the actual cell division process (mitosis), the chromosomal DNA becomes highly compacted,

and the pairs of sister chromatids can be seen in the electron microscope, as depicted here. (c) Light-microscope image of a chromosomal spread from a cultured human male lymphoid cell arrested in the metaphase stage of mitosis by treatment with the microtubule-depolymerizing drug colcemid. There is a single copy of the duplicated X and Y chromosomes and two copies of each of the others.

The Endoplasmic Reticulum Is the Site of Synthesis of Most Membrane and Secreted Proteins as Well as Many Lipids

We noted earlier that each type of organelle membrane, and the interior space of each organelle, contains a discrete set of proteins that enable it to carry out its specific function. Indeed, about a third of the proteins in a typical eukaryotic cell are found in the plasma membrane, in a specific organelle membrane, or in the interior space of an organelle. Thus there are a large number of proteins (and lipids) that have to be synthesized and sorted to different locations — about one-third of the proteome, the totality of proteins made by a eukaryotic cell. The synthesis of lipids, secreted proteins, and many types of membrane proteins occurs on the organelle with the largest membrane surface in a eukaryotic cell, the **endoplasmic reticulum (ER)**.

The ER is an extensive network of closed, flattened, membrane-bounded sacs called **cisternae** (Figure 1-18; see also Figure 1-16a),

and is generally subdivided into regions termed the **smooth** and **rough endoplasmic reticulum**. The smooth ER is smooth because it lacks ribosomes; it is the site of synthesis of fatty acids and phospholipids. In contrast, the cytosolic side of the rough endoplasmic reticulum is studded with ribosomes; these ribosomes synthesize certain membrane and organelle proteins and virtually all proteins that are to be secreted from the cell (see Chapter 13). Newly made membrane proteins become associated with the rough ER membrane, and proteins to be secreted accumulate in the **lumen**, the aqueous interior of the organelle.

FIGURE 1-18 The Golgi complex and rough endoplasmic reticulum. An electron micrograph of a section of a human liver cell shows the abundant ribosome-studded rough endoplasmic reticulum and the Golgi complex, as well as many ribosomes free in the cytosol.

The Golgi Complex Sorts Secreted Proteins and Many Membrane Proteins to Their Final Destinations in the Cell

Several minutes after secreted proteins and membrane proteins are synthesized in the rough ER, most of them leave the organelle within small, membrane-bounded transport vesicles about 50 nanometers (0.05 μm) in diameter. These vesicles, which bud from regions of the rough ER not coated with ribosomes, carry the proteins to another membrane-bounded organelle, the Golgi complex (see Figure 1-18). As detailed in Chapter 14, secreted proteins and membrane proteins undergo a series of enzyme-catalyzed chemical modifications in the Golgi complex that are essential for these proteins to function normally.

After these proteins are modified in the Golgi complex, they are transported out of the complex by a second set of small, ~0.05-μm diameter vesicles, which bud from one side of the Golgi complex. These vesicles carry proteins to the plasma membrane or to lysosomes or to other organelles, or they release proteins from the cell into the extracellular space. How intracellular transport vesicles are formed, how they target specific proteins to specific membranes, and how they fuse with these membranes to deliver their contents is also discussed in Chapter 14.

Endosomes Bring Proteins and Particles from the Outside into Cells

Although transport proteins in the plasma membrane mediate the movement of ions and small molecules into the cell across the phospholipid bilayer, proteins, particles such as viruses, and some other soluble macromolecules in the extracellular milieu are brought into the cell by **endocytosis**. In this process, a segment of the plasma membrane buds inward — a process termed *invagination* — into a *coated pit*, whose cytosolic face is lined by a specific set of proteins that cause these vesicles to form. The pit pinches from the membrane into a small, ~0.05-μm-diameter membrane-bounded vesicle that contains the extracellular material. The vesicle is delivered to and fuses with an **endosome**, a sorting station formed of a vesicle and membrane-lined tubules (Figure 1-19). From this compartment, some membrane proteins are recycled back to the plasma membrane; other membrane proteins are transported in vesicles that eventually fuse with **lysosomes** for degradation. The entire endocytic pathway is described in detail in Chapter 14.

FIGURE 1-19 Endosomes and other cellular structures deliver materials to lysosomes. Schematic overview of three pathways by which materials are moved to lysosomes. Within the acidic lumen of a lysosome, hydrolytic enzymes degrade proteins, nucleic acids, lipids, and other large molecules.

1 Soluble macromolecules and molecules bound to proteins on the cell surface are taken into the cell by invagination of segments of the plasma membrane and delivered to lysosomes through the endocytic pathway; endosomes fuse with lysosomes, intermixing their contents.

2 Whole cells and other large, insoluble particles move from the cell surface to lysosomes through the phagocytic pathway; phagosomes fuse with lysosomes, intermixing their contents.

3 Worn-out organelles and bulk cytoplasm are delivered to lysosomes through the autophagic pathway.

Lysosomes Are Cellular Recycling Centers

Lysosomes contain a group of enzymes that degrade polymers into their monomeric subunits. Found exclusively in animal cells, lysosomes are responsible for degrading many components that have become obsolete for the cell or organism. As examples, nucleases degrade RNA and DNA into their mononucleotide building blocks; proteases degrade a variety of proteins and peptides into amino acids; phosphatases remove phosphate groups from mononucleotides, phospholipids, and other compounds; still other enzymes degrade complex polysaccharides and lipids into smaller units. The small molecules so generated are usually reutilized by the cell to make new proteins, nucleic acids, and carbohydrates. All of these lysosomal enzymes, collectively termed *acid hydrolases*, work most efficiently at acidic pH values. The acidic pH $\sim$5.0 found within lysosomes helps to denature proteins, making them accessible to the action of the lysosomal hydrolases. These enzymes are less active at the neutral pH of cells and most extracellular fluids. Thus if a lysosome releases its enzymes into the cytosol, where the pH is between 7.0 and 7.3, they cause little degradation of cytosolic components. The low pH of lysosomes is generated by proteins in the lysosomal membrane that pump protons (H^+ ions) from the cytosol into the lumen of the lysosome, as detailed in Chapter 11. Lysosomes provide an excellent example of the ability of intracellular membranes to form closed compartments in which the

composition of the lumen (the aqueous interior of the compartment) differs substantially from that of the surrounding cytosol.

Aged organelles are degraded in a lysosome by a process called **autophagy** ("eating oneself"). Materials taken into a cell by endocytosis or phagocytosis may also be degraded in lysosomes (see Figure 1-19). In **phagocytosis**, large, insoluble particles (e.g., bacteria) are enveloped by the plasma membrane and internalized, and the particles are quickly delivered to lysosomes for degradation. Cytosolic and nuclear proteins generally are not degraded in lysosomes, but rather in proteasomes, large multiprotein complexes in the cytosol (see Chapter 3).

Plant Vacuoles Store Water, Ions, and Small-Molecule Nutrients Such as Sugars and Amino Acids

Most plant cells contain at least one membrane-bounded **vacuole**. A variety of membrane proteins in the vacuolar membrane transport water, ions, and small-molecule nutrients such as sugars and amino acids from the cytosol into the vacuole lumen. The number and size of vacuoles depend on both the type of cell and its stage of development; a single vacuole may occupy as much as 80 percent of a mature plant cell (Figure 1-20). Like that of a lysosome, the lumen

of a vacuole contains a battery of degradative enzymes and has an acidic pH, which is maintained by similar transport proteins in the vacuolar membrane. Thus plant vacuoles may also have a degradative function similar to that of lysosomes in animal cells. Similar storage vacuoles are found in green algae and in many microorganisms such as fungi.

Biophoto Associates/Science Source.

FIGURE 1-20 Electron micrograph of a thin section of a leaf cell. In this cell, a single large vacuole occupies much of the cell volume. Parts of five chloroplasts and the cell wall are also visible. Note the internal subcompartments in the chloroplasts.

Peroxisomes and Plant Glyoxisomes Metabolize Fatty Acids and Other Small Molecules Without Producing ATP from ADP and P_i

All animal cells (except erythrocytes) and many plant and fungal cells contain **peroxisomes**, a class of roughly spherical organelles 0.2–1.0 μm in diameter. A major function of peroxisomes is to catabolize (degrade) long-chain fatty acids to CO_2. As discussed in Chapter 12, mitochondria also contain enzymes that degrade fatty acids to CO_2, but in contrast to mitochondria, peroxisomes do not synthesize ATP from ADP and P_i. Several of the enzymes in peroxisomes are *oxidases* that use molecular oxygen to add oxygen atoms — a process termed *oxidation* — to a variety of organic substances and in the process form hydrogen peroxide (H_2O_2), a corrosive substance. Peroxisomes also contain copious amounts of the enzyme *catalase*, which degrades hydrogen peroxide to yield water and oxygen (see Chapter 12).

Plant seeds contain *glyoxisomes*, small organelles that oxidize stored lipids as a source of carbon and energy for growth. They are similar to peroxisomes and contain many of the same types of enzymes as well as additional ones used to convert fatty acids into glucose precursors.

Mitochondria Are the Principal Sites of ATP Production in Aerobic Cells

The activities of all parts of a cell are powered by the energy stored in ATP molecules. The main sites of ATP production during aerobic metabolism (metabolism requiring oxygen) are the **mitochondria** (Figure 1-21), which can occupy up to 25 percent of the volume of the cytoplasm. These complex organelles are generally exceeded in size only by the nucleus, vacuoles, and chloroplasts. The two membranes that are found in all mitochondria differ in composition and function. The **outer mitochondrial membrane** contains proteins that allow many molecules to move from the cytosol to the **intermembrane space** between the inner and outer membrane. The **inner mitochondrial membrane**, which is much less permeable, is about 20 percent lipid and 80 percent protein — a proportion of protein that is higher than those in other cellular membranes. The surface area of the inner membrane is greatly increased by a large number of infoldings, or **cristae**, that protrude into the **matrix**, the central aqueous space inside the inner membrane. The large

number of proteins in the inner membrane are needed to complete the aerobic degradation of fuels to form ATP from ADP and inorganic phosphate (see Figure 1-7 and Chapter 12).

FIGURE 1-21 Electron micrograph of a mitochondrion in a pancreas cell. The smooth outer membrane forms the outside boundary of the mitochondrion. The inner membrane is distinct from the outer membrane and is highly invaginated to form sheets and tubes called *cristae*; ATP is produced by proteins embedded in the membranes of the cristae. The aqueous space between the inner and outer membranes (the intermembrane space) and the space inside the inner membrane (the matrix) each contain specific proteins important for the metabolism of sugars, lipids, and other molecules.

In non-photosynthetic cells, the principal fuels for ATP synthesis are fatty acids and glucose. The complete aerobic degradation of 1 molecule of glucose to carbon dioxide and water is coupled to the synthesis of as many as 30 molecules of ATP from ADP and inorganic phosphate (see Figure 1-7). In eukaryotic cells, the initial stages of glucose degradation take place in the cytosol, where 2 ATP molecules per glucose molecule are generated. The terminal stages of oxidation and ATP synthesis are carried out by enzymes in the mitochondrial matrix and inner membrane (see Chapter 12); as many as 28 ATP molecules per glucose molecule are generated in mitochondria. Similarly, virtually all the ATP formed in the oxidation of fatty acids to carbon dioxide is generated in mitochondria. Thus mitochondria can be regarded as the power plants of the cell.

As discussed in Chapter 12, the popular *endosymbiont hypothesis* postulates that mitochondria originated by endocytosis of an ancient aerobic bacterium by the precursor of a eukaryotic cell; the bacterial plasma membrane evolved to become the inner mitochondrial membrane. Indeed, mitochondria contain small DNA molecules that encode a small number of mitochondrial proteins and that are thought to have descended from the DNA genome of this ancient bacterium.

Chloroplasts Contain Internal Compartments in Which Photosynthesis Takes Place

Except for vacuoles, **chloroplasts** are the largest and the most characteristic organelles in the cells of plants and green algae (see Figure 1-20). The endosymbiont hypothesis (see Chapter 12) posits that these organelles originated by endocytosis of a primitive photosynthetic bacterium. Chloroplasts can be as long as 10 μm and are typically 0.5–2 μm wide, but they vary in size and shape in different cells, especially among the algae. In addition to the inner and outer membranes that bound a chloroplast, this organelle also contains an extensive internal system of interconnected membrane-bounded vesicles called **thylakoids**, which are flattened to form disks. Thylakoids often form stacks called *grana* and are embedded in an aqueous matrix termed the *stroma*. The thylakoid membranes contain green pigments (chlorophylls) and other pigments that absorb light, as well as enzymes that generate ATP from ADP and inorganic phosphate during photosynthesis. Some of the ATP is used to convert carbon dioxide into three-carbon intermediates by enzymes located in the stroma; the intermediates are then exported to the cytosol and converted into sugars.

The molecular mechanisms by which ATP is formed in mitochondria and chloroplasts are very similar, as explained in Chapter 12. Besides being surrounded by two membranes,

chloroplasts and mitochondria have other features in common: both often migrate from place to place within cells, and both contain their own DNA, which encodes some of the key organelle proteins (see Chapter 12). The proteins encoded by mitochondrial or chloroplast DNA are synthesized on ribosomes within the organelles. However, most of the proteins in each organelle are encoded in nuclear DNA and are synthesized in the cytosol; these proteins are then incorporated into the organelles and directed to the correct membrane or space by processes described in Chapter 13.

Many Organelle-Like Structures Are Unbounded by a Membrane

In addition to membrane-enveloped organelles, eukaryotic cells contain a variety of substructures in which important biochemical functions are concentrated but that are not surrounded by a membrane. These membraneless organelles range in size from 0.1–3 micrometers in diameter. One ubiquitous example is the **nucleolus**, a subcompartment of the nucleus where ribosomal RNA is synthesized and ribosomes are assembled (see Figure 1-16b and Chapter 9). Other subcompartments of the nucleus have recently been made visible by the new microscopic techniques detailed in Chapter 4. These include **nuclear speckles**, sites where RNA

polymerase and other gene regulatory proteins are concentrated and where messenger RNAs are synthesized and processed.

Subcompartments of the cytosol include **P bodies**, sites where many messenger RNAs are degraded, and **cytosolic stress granules**, membraneless organelles where some messenger RNAs are stored awaiting a signal to be translated into a protein.

Although much remains to be learned about the organization of these membraneless organelles, recent evidence suggests that they are formed by many weak but specific interactions between proteins and nucleic acids that exclude the surrounding aqueous phase. Their properties are characteristic of liquid droplets suspended in another, chemically distinct liquid, and they are often referred to as **biomolecular condensates** (see Chapter 3). Their structures are highly dynamic, in that proteins can diffuse into and out of these condensates. Clearly much needs to be learned about their formation, structure, and biological functions.

All Eukaryotic Cells Use a Similar Cycle to Regulate Their Division

Unicellular eukaryotes, animals, and plants all use essentially the same **cell cycle**, the series of events that prepares a cell to divide, and the same actual division process, called **mitosis**. The eukaryotic cell cycle is commonly divided into four phases (Figure 1-22). The

chromosomes and the DNA they carry are duplicated during the **S (synthesis) phase**. The replicated chromosomes condense (see Figure 1-17) and separate during the **M (mitotic) phase** during which the cell divides, and each daughter cell gets one copy of each chromosome. The M and S phases are separated by two gap phases, the **G_1 phase** and the **G_2 phase**, during which mRNAs, proteins, lipids, and other cell constituents are made and the cell increases in size.

FIGURE 1-22 During growth, all eukaryotic cells continually progress through the four phases of the cell cycle. In proliferating cells, the four phases of the cell cycle proceed successively. In humans, the cycle takes from 10 to 20 hours depending on cell type and developmental state. Yeasts divide much faster. During interphase, which consists of the G_1, S, and G_2 phases, the cell roughly doubles its mass. Replication of DNA during the S phase leaves the cell with two copies of each type of chromosome (see Figure 1-17c). In the mitotic (M) phase, the chromosomes are evenly partitioned into two daughter cells, and in

most cases the cytoplasm divides roughly in half by division along the midline. Under certain conditions, such as starvation or when a tissue has reached its final size, cells will stop cycling and remain in a waiting state called G_0. Some types of cells in G_0 can re-enter the cell cycle if conditions change.

Under optimal conditions, some bacteria, such as *E. coli*, can divide to form two daughter cells once every 20 minutes. Most eukaryotic cells take considerably longer to grow and divide, generally several hours. Moreover, the cell cycle in eukaryotes is highly regulated (see Chapter 19). This tight control prevents imbalanced, excessive growth of cells and tissues if essential nutrients or certain hormonal signals are lacking. Some highly specialized cells in adult animals, such as neurons and heart muscle cells, divide rarely, if at all. However, an organism usually replaces worn-out cells or makes more cells in response to a new need — for example, new muscle cells are generated from undifferentiated stem cells in response to exercise or damage. Another example is the formation of additional red blood cells when a person ascends to a higher altitude and needs more capacity to capture oxygen. The fundamental defect in cancer is loss of the ability to control the growth and division of cells. In Chapter 25, we examine the molecular and cellular events that lead to inappropriate, uncontrolled proliferation of cells.

1.4 Unicellular Eukaryotic Organisms Widely Used in Cell Biology Research

Our current understanding of the molecular functioning of eukaryotic cells largely rests on studies of just a few types of organisms, often termed *model organisms* (Figure 1-23). Because of the evolutionary conservation of genes, proteins, organelles, cell types, and so forth, discoveries about biological structures and functions obtained with one experimental organism often apply to others. Thus researchers generally conduct studies with the organism that is most suitable for rapidly and completely answering the question being posed, knowing that the results obtained in one organism are likely to be broadly applicable.

FIGURE 1-23 Many eukaryotic organisms used in cell biology research have advantages for certain types of studies. The yeast *Saccharomyces cerevisiae* (a) has the cellular organization of a eukaryote but is a relatively simple single-celled organism that is easy to grow and to manipulate genetically. The green alga *Chlamydomonas reinhardtii* (b) is widely used to study photosynthesis and the structure and function of flagella. In the roundworm *Caenorhabditis elegans* (c), which has a small number of cells arranged in a nearly identical way in every worm, the formation of each individual cell can be traced. The fruit fly *Drosophila melanogaster* (d), first used to discover the properties of chromosomes, has been especially valuable in identifying genes that control embryonic development. Many of these genes are evolutionarily conserved in humans. Planaria (e) are flatworms that can regenerate any part of the body that is cut off, including the head and the photoreceptors.

The stem cells that give rise to their new cells and tissues are widely studied. The zebrafish *Danio rerio* (f) is used for rapid genetic screens to identify genes that control vertebrate development and organogenesis. Of the experimental animal systems, mice (*Mus musculus*) (g) are evolutionarily the closest to humans and have thus provided models for studying numerous human genetic and infectious diseases. The mustard-family weed *Arabidopsis thaliana* (h) has been used for genetic screens to identify genes involved in nearly every aspect of plant life.

As we have seen, bacteria are excellent experimental systems for studies of several cellular functions, but they lack the organelles found in eukaryotes. Unicellular eukaryotes such as yeasts are used to study many fundamental aspects of eukaryotic cell structure and function. Metazoan organisms such as the roundworm, fruit fly, and mouse are required to study more complex tissue and organ systems and development. As we will see in this section and the next, these and other metazoans are widely used to understand complex cell systems and mechanisms.

Yeasts Are Used to Study Fundamental Aspects of Eukaryotic Cell Structure and Function

One group of single-celled eukaryotes, the yeasts, has proven exceptionally useful in molecular and genetic analysis of eukaryotic cell formation and function. Yeasts and their multicellular cousins, the molds, are fungi. Fungi have important ecological roles in

breaking down plant and animal remains for reuse. They also make numerous antibiotics and are used in the manufacture of bread, beer, and wine.

The common yeast used to make bread and beer, *Saccharomyces cerevisiae* (Figure 1-24a), appears frequently in this book because it has proved to be an extremely useful experimental organism. *S. cerevisiae* is a spherical cell that divides by budding of a daughter cell from a side of the mother cell, eventually breaking free (Figure 1-24a, b). Homologs of many of the approximately 6600 different proteins expressed in an *S. cerevisiae* cell (see Table 1-2) are found in most, if not all, eukaryotes and are important for cell division or for the functioning of individual eukaryotic organelles. Much of what we know of the proteins in the endoplasmic reticulum and Golgi complex that promote protein secretion was elucidated first in genetic studies of yeasts (see Chapter 14). Yeasts were also essential for the identification of many proteins that regulate the cell cycle and catalyze DNA replication and transcription.

FIGURE 1-24 The yeasts *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe* can be haploid or diploid and can reproduce sexually or asexually. (a) Scanning electron micrograph of the budding yeast *Saccharomyces cerevisiae*. These cells grow by an unusual type of mitosis termed *Smitotic budding*. One daughter nucleus remains in the mother cell; the other daughter nucleus is transported into the bud, which grows in size and soon is released as a new cell. After each bud cell breaks free, a scar is left at the budding site, so the number of previous buds on the parent cell can be counted. The orange-colored cells are bacteria. (b) Haploid *S. cerevisiae* cells can have different mating types, called **a** (blue) and α (orange). Both types contain a single copy of each yeast chromosome, half the usual number, and grow by mitotic budding. Two haploid cells that differ in mating type, one **a** and one α, can fuse together to form an **a**/α diploid cell. An **a** haploid cell secretes a pheromone protein termed the **a** *mating factor* that binds to a receptor protein on the surface of an α cell, and conversely an α cell secretes the α factor protein that binds to a different surface receptor on the **a** cell. Thus each type of cell recognizes the mating factor produced by the opposite type, and these hormones trigger fusion of the **a** and α cell. The **a**/α diploid cell contains two copies of each chromosome; diploid cells can multiply by mitotic budding in a manner similar to that of the haploid cells. Under starvation conditions, a diploid cell can undergo meiosis, a special type of cell division, to form four haploid ascospores. Rupture of an ascus releases four haploid spores, which can germinate into haploid **a** and α cells. These cells can also multiply asexually. (c) Both haploid and diploid *Schizosaccharomyces pombe* cells have a mitotic division cycle different from that of *S.*

cerevisiae, one that more resembles that of human cells than that of *S. cerevisiae*. Bracket indicates a cell undergoing mitotic division.

The yeast species *Schizosaccharomyces pombe* diverged from *S. cerevisiae* between 300 and 600 million years ago and is also widely used in research. Unlike *S. cerevisiae, S. pombe* is a rod-shaped cell that grows by elongation at the ends; like human cells it divides by division at the cell midpoint (Figure 1-24c; see also Figure 1-22). Like human cells, but unlike *S. cerevisiae*, most genes in *S. pombe* have introns that are removed from RNA transcripts by processing in the nucleus (see Figure 1-10). *S. cerevisiae, S. pombe*, and other yeasts offer many advantages to molecular and cellular biologists:

- Vast numbers of yeast cells can be grown easily and cheaply in culture from a single cell; the cells in such **clones** are genetically identical and have the same biochemical properties. Individual proteins or multiprotein complexes can be purified from large amounts of cells and then studied in detail.
- Yeast cells may be either haploid (containing one copy of each chromosome) or diploid (containing two copies of each chromosome), and both forms can divide by mitosis; this ability makes isolating and characterizing mutations in genes encoding essential yeast cell proteins relatively straightforward, as we see in the next section.
- Yeasts, like many organisms, have a sexual cycle that allows exchange of genes between cells. Under starvation conditions, diploid cells undergo meiosis (see Chapter 19) to form haploid

daughter cells. Haploid *S. cerevisiae* cells are of two types, **a** and α cells. If haploid **a** and α cells come close to one another, they secrete hormones that induce the two cells to fuse, forming an **a**/α diploid cell that contains two copies of each chromosome, one from each parent cell (Figure 1-24b).

With the use of a single species such as *S. cerevisiae* as an experimental organism, results from studies carried out by tens of thousands of scientists worldwide, using multiple investigational techniques, can be combined to yield a deeper level of understanding of a single type of cell. As we will see many times in this book, conclusions based on studies of *S. cerevisiae* and *S. pombe* have often proved true for all eukaryotes. These conclusions have provided a basis for exploring the evolution of more complex processes in multicellular animals and plants.

Mutations in Yeast Led to the Identification of Key Cell Cycle Proteins

Biochemical studies can tell us much about an individual protein, but they cannot prove that it is required for cell division or any other cell process. The importance of a protein is demonstrated most firmly if a mutation that prevents its synthesis or makes it nonfunctional adversely affects the process under study.

In a classical genetics approach, scientists isolate and characterize mutants that lack the ability to do something a normal organism can do. Often large genetic screens are done to look for many different mutant individuals (e.g., fruit flies, yeast cells) that are unable to complete a certain process, such as cell division or muscle formation. Mutations are usually produced by treatment with a *mutagen*, a chemical or physical agent that promotes mutations in a largely random fashion. However, inactivating genes that encode proteins for an essential cell process will kill the organism. How then can we isolate and maintain mutant organisms or cells that are defective in some process, such as cell division or protein secretion, that is essential for survival?

One way is to isolate organisms with a **temperature-sensitive mutation**. These mutants are able to grow at the *permissive temperature*, but not at another, usually higher temperature, the *nonpermissive temperature*. Normal cells can grow at either temperature. In most cases, a temperature-sensitive mutant produces an altered protein that works at the permissive temperature but unfolds and is nonfunctional at the nonpermissive temperature. Screens for temperature-sensitive mutations are most readily done with haploid organisms such as yeasts because they have only one copy of each gene, and thus a mutation in it will immediately have a consequence.

By analyzing the effects of numerous different temperature-sensitive mutations that altered the division of haploid yeast cells, geneticists discovered most of the genes necessary for cell growth and division without knowing anything, initially, about which proteins they encode or how these proteins participate in the process. In general, the great power of genetics is to reveal the existence and relevance of all proteins required for a particular cell function without prior knowledge of their biochemical identity or molecular function. These mutation-defined genes can be isolated using recombinant DNA techniques discussed in Chapter 6. With the isolated genes in hand, the encoded proteins can be produced in a test tube or in engineered bacteria or cultured cells. In this way, biochemists can investigate whether the genes necessary for cell division encode proteins that associate with other proteins or DNA or catalyze particular chemical reactions during cell division (see Chapter 19).

Most of these yeast cell cycle genes are found in human cells as well, and the encoded proteins have similar amino acid sequences. Proteins from different organisms, but with similar amino acid sequences, are said to be **homologous**; such proteins often have the same or similar functions. Remarkably, it has been shown that a human protein that regulates the cell cycle, when expressed in a mutant yeast defective in the homologous yeast protein, is able to rescue the defect of the mutant yeast (i.e., to allow the cell to grow normally), thus demonstrating the protein's ability to function in a very different type of eukaryotic cell. This experimental result,

which together with identification and characterization of many other cell cycle genes garnered a Nobel Prize for Paul Nurse, was especially notable because the common ancestor of present-day yeasts, plants, and humans is thought to have lived over a billion years ago. Clearly the eukaryotic cell cycle and many of the genes and proteins that catalyze and regulate it evolved early in biological evolution and have remained quite constant over a very long period of evolutionary time. Subsequent studies showed that mutations in many yeast cell cycle proteins that allow uncontrolled cell growth also frequently occur in human cancers (see Chapter 25), again attesting to the important conserved functions of these proteins in all eukaryotes.

Studies in the Alga *Chlamydomonas reinhardtii* Led to the Development of a Powerful Technique to Study Brain Function

The green unicellular alga *Chlamydomonas reinhardtii* (see Figure 1-23b), which swims using its two long flagella, is widely used in studies of the structure, function, and assembly of this organelle. In part because of the powerful genetic techniques now available, *Chlamydomonas* is also used in studies of chloroplast formation and photosynthesis. The *Chlamydomonas* genome (see Table 1-2) encodes many more proteins than do those of yeasts, including flagellar

proteins and proteins needed to build a chloroplast, organelles not found in yeasts.

One important outcome of the use of this experimental organism came from studies of phototaxis, the behavior in which an organism moves toward or away from a source of light. *Chlamydomonas* needs to move toward light to undergo photosynthesis and thus generate the energy it needs to grow and divide, but light that is too intense repels it, as it causes damage to the chloroplast. Studies of *Chlamydomonas* phototaxis led to the discovery of two proteins in its plasma membrane that, when they absorb light, open a channel in the membrane that allows ions such as Ca^{2+} to flow from the extracellular medium into the cytosol, triggering phototactic responses. As detailed in Chapter 23, recombinant DNA techniques have been used to express one such protein in specific neurons in the mouse brain, allowing investigators to activate just one or a few cells in the brain using a point source of light. Thus studies on this humble alga have led to the development of an important experimental system — optogenetics — for the study of brain function.

The Parasite That Causes Malaria Has Novel Organelles That Allow It to Undergo a Remarkable Life Cycle

Whereas yeasts are used in the manufacture of bread, beer, wine, and cheese, some unicellular eukaryotes cause major human diseases and are widely studied in an attempt to develop vaccines or drugs that will kill them but not injure their human host. *Entamoeba histolytica* causes dysentery; *Trichomonas vaginalis*, vaginitis; and *Trypanosoma brucei*, sleeping sickness. Each year the worst of these protozoans, *Plasmodium falciparum* and related species, cause more than 200 million new cases of malaria, a disease that kills 1.5 million to 3 million people annually. These protozoans inhabit mammals and mosquitoes alternately, changing their morphology and behavior in response to signals in each of these environments.

The complex life cycle of *Plasmodium* dramatically illustrates how a single cell can adapt to multiple environments (Figure 1-25a). Additionally, the *merozoite* form that infects human red blood cells contains several organelles, not found in most eukaryotes, that enable the parasite to invade a red blood cell, including the rhoptries, polar ring, and micronemes, as well as a fuzzy surface coat on the outside of the cell (Figure 1-25b, c). Entry of the parasite into a red blood cell is initiated by binding of certain parasite cell-surface proteins to proteins on the red blood cell surface, accompanied by the secretion of proteins stored in the micronemes and rhoptries. A tight junction is formed between the two plasma membranes, and the fuzzy coat is lost as parasites enter the host cell (Figure 1-25c).

FIGURE 1-25 *Plasmodium* species, the parasites that cause malaria, are single-celled protozoans with a remarkable life cycle. Many *Plasmodium* species are known, and they can infect a variety of animals, cycling between insect and vertebrate hosts. The four species that cause malaria in humans undergo several dramatic transformations within their human and mosquito hosts. (a) Diagram of the life cycle. Like many yeasts, *Plasmodium* spends most of its life cycle as a haploid organism, with a single copy of most genes. Step 1: Haploid sporozoites enter a human host when an infected *Anopheles* mosquito bites a person. Step 2: They migrate to the liver, where they develop into merozoites, which are released into the blood. Merozoites differ substantially from sporozoites, so this transformation is a metamorphosis (Greek, “to transform” or “many shapes”). Step 3: Circulating merozoites invade red blood cells (RBCs) and reproduce within them. Proteins produced by some *Plasmodium* species move to the surface of infected RBCs, causing the cells to adhere to the walls of blood vessels. This prevents infected RBCs from circulating to the spleen, where cells of the immune system would destroy the RBCs and the *Plasmodium*

organisms they harbor. Step 4: After growing and reproducing in RBCs for a period of time characteristic of each *Plasmodium* species, the merozoites suddenly burst forth in synchrony from large numbers of infected cells. It is this event that brings on the fevers and shaking chills that are the well-known symptoms of malaria. Some of the released merozoites infect additional RBCs, creating a cycle of reproduction and infection. Step 5: Eventually, some merozoites develop into male and female gametocytes, another metamorphosis. These cells do not replicate further, waiting to be transferred to an *Anopheles* mosquito during a bloodmeal. Step 6: In the mosquito's stomach, the gametocytes are transformed into microgametocytes (sperm) or macrogametocytes (eggs), yet another metamorphosis marked by development of slender motile sperm. Step 7: Fusion of sperm and eggs generates the diploid zygotes, which implant into the lining of the stomach and grow into oocysts. Within the oocysts, parasites undergo meiosis, returning to a haploid chromosome content, followed by several rounds of mitosis that essentially are factories for producing sporozoites. Step 8: Rupture of an oocyst releases thousands of sporozoites, which migrate to the salivary glands, setting the stage for infection of another human host. (b) Organelles of the *Plasmodium vivax* merozoite. Some of these organelles are found only in *Plasmodium* and related eukaryotic parasitic microorganisms. (c) Section of a *Plasmodium vivax* merozoite invading a human red blood cell. See A. Cowman and B. Crabb, 2006, *Cell* **124**:755–766.

All the cellular transformations that occur during the *Plasmodium* life cycle are governed by instructions encoded in the genetic material of this parasite (see Table 1-2). The *Plasmodium* genome has about the same number of protein-coding genes as the yeast *S. cerevisiae*, but about two-thirds of the *Plasmodium* genes appear to be unique to this and related parasites. Their many unique genes attest to the great evolutionary distance between these parasites, members of the genus **Apicomplexa** (see Figure 1-1), and most other eukaryotes as well as the presence of unusual organelles required for their complex life cycles.

1.5 Metazoan Structure, Function, Evolution, and Differentiation

The evolution of multicellular organisms most likely began when cells remained associated in small colonies after division instead of separating into individual cells. A few prokaryotes and the colonial algae *Volvox* (see Figure 1-3d), as well as many fungi and slime molds, exhibit such rudimentary social behavior. The full flowering of multicellularity, however, occurred in the eukaryotic organisms called *metazoans* whose cells became differentiated and organized into groups, or tissues, in which the different cells performed specialized functions. In this section, we describe some of the principal features of metazoans: adhesion of cells to each other, communication between cells, and regulation of development such that the correct cells are produced at the right time in the right place in the organism.

Multicellularity Requires Cell-Cell and Cell-Matrix Adhesions

The cells of higher plants are encased in a network of chambers formed by the interlocking cell walls surrounding the cells and are connected by cytoplasmic bridges called **plasmodesmata** (see Figure 1-13a). Animal cells are often "glued" together into a chain, a ball, or a sheet by cell-adhesion proteins on their surfaces, often

called **cell-adhesion molecules**, or **CAMs** (see Figure 1-4d and Chapter 20). Some CAMs bind cells to one another; other types bind cells to the fibrous proteins and sugar polymers (polysaccharides) that form the **extracellular matrix**, forming a cohesive unit. In animals, the matrix cushions cells and allows nutrients to diffuse toward them and waste products to diffuse away. A specialized, especially tough matrix called the **basal lamina**, made up of polysaccharides and multiple proteins such as collagen, forms a supporting layer underlying cell sheets and prevents the cell aggregates from ripping apart (see Figure 1-4). Many CAMs and extracellular-matrix proteins found in humans also occur in invertebrates, indicating their importance during metazoan evolution.

Similarly, many of the proteins and small molecules used by metazoans as signaling molecules are conserved in humans and many invertebrates, as are their **receptors**, the cellular proteins that bind to these signaling molecules and trigger an effect in the receiving cell.

Epithelia Originated Early in Evolution

Metazoans, which are thought to have evolved in an ocean-like, saline environment, had to solve a fundamental problem: separating the inside of the organism from the outside. The external surfaces of all metazoan animals, as well as the surfaces of their internal

organs, are covered by a sheet-like layer of tissue called an **epithelium**. Epithelia commonly serve as barriers and protective surfaces, as exemplified by the sheets of epidermal cells that form the skin (see Figure 1-4). Other epithelia are one cell-layer thick and line internal organs such as the small intestine, where they are crucial for uptake and transport of the products of digestion (e.g., glucose and amino acids) into the blood (see Chapter 11). As discussed in Chapter 20, epithelia in different body locations have characteristic morphologies and functions.

Cells that form epithelial tissues are said to be *polarized* because their plasma membranes are organized into at least two discrete regions. Typically, the distinct surfaces of a polarized epithelial cell are the **apical** surface — the "top" of the cell facing the external world — and the **basal** and **lateral** (collectively, **basolateral**) surfaces that face the organism's interior. As shown in Figure 1-4, the basal surface usually contacts an underlying extracellular matrix, the basal lamina. As discussed in Chapter 20, specialized junction proteins in the basolateral plasma membrane link adjacent cells together and also bind the cells to the basal lamina.

Cells Are Organized into Tissues and Tissues into Organs

Cells in metazoans do not work in isolation; specialized groups of differentiated cells often form tissues, which are themselves the major components of organs. For example, a blood vessel is composed of layers of different types of tissue. The lumen of a small blood vessel is lined with a sheet-like layer of endothelial cells, or **endothelium**, which prevents blood cells from leaking out (Figure 1-26). A layer of smooth muscle tissue encircles the endothelium and basal lamina and contracts to limit blood flow. During times of fright, constriction of smaller peripheral vessels forces more blood to the vital organs. The muscle layer of a blood vessel is wrapped in an outer layer of connective tissue, a network of fibers and cells that encases the vessel walls and protects them from stretching and rupture.

SPL/Science Source.

FIGURE 1-26 All organs are organized arrangements of various tissues, as illustrated in this cross section of a small artery (arteriole). Blood flows through the vessel lumen, which is lined by a thin sheet of endothelial cells forming the endothelium and by the underlying basal lamina. This tissue adheres to the overlying layer of smooth muscle tissue; contraction of the muscle layer controls blood flow through the vessel. A fibrillar layer of connective tissue surrounds the vessel and connects it to other tissues.

This hierarchy of tissues is copied in other blood vessels, which differ mainly in the thickness of the layers. The wall of a major artery must withstand much stress and is therefore thicker than that of a minor vessel. The strategy of grouping and layering different

tissues is used to build other complex organs as well. In each case, the function of the organ is determined by the specific functions of its component tissues, and each type of cell in a tissue produces the specific groups of proteins that enable the tissue to carry out its functions.

Genomics Has Revealed Important Aspects of Metazoan Evolution and Cell Function

Metazoans — be they invertebrates such as the fruit fly *D. melanogaster* and the roundworm *C. elegans*, or vertebrates such as mice and humans — contain between 13,000 and 26,000 protein-coding genes, about two to four times as many as a yeast (see Table 1-2). Sequencing of entire genomes has shown that many of these genes are conserved among the metazoans, and genetic studies have shown that many of them are essential for the formation and function of specific tissues and organs. Thus many of the organisms listed in Table 1-2 are used to study the roles of these conserved proteins in cell development and function.

The human and mouse genomes encode about the same number of proteins as those of the roundworm *C. elegans*, frogs, and fish, yet mammalian cells contain about 30 times the DNA of a roundworm and two to three times the DNA of frogs and fish. Only about 10

percent of human DNA encodes proteins. We now know that much of the remaining 90 percent has important functions. As detailed in Chapter 8, many DNA segments, termed *enhancers*, bind proteins that regulate expression of nearby genes. The expression of many genes is controlled by large numbers of such regulatory sequences; control by multiple enhancers allows each mammalian gene to make the precise amount of mRNA and protein needed in each of many different types of cells.

Other segments of DNA are used to synthesize the thousands of RNA molecules that do not direct the synthesis of proteins and whose function in regulating gene expression is only now being uncovered. As an example, hundreds of different kinds of micro-RNAs, 20 to 25 nucleotides long, are abundant in metazoan cells. Each microRNA binds to and represses the activity of a specific set of target mRNAs, either by inhibiting the ability of these mRNAs to be translated into proteins or by triggering their degradation (see Chapter 9). By this means, each of these small RNAs can indirectly regulate the activity of many genes.

Some of this nonprotein-coding DNA probably regulates expression of genes that make us uniquely human. Indeed, fish and humans have about the same number of protein-coding genes — about 20,000 — yet as noted above, the human genome is over twice the size of that in fish (see Table 1-2). The human brain can perform complex mental processes such as reading and writing a textbook.

Somehow these 20,000 human genes are exquisitely regulated such that humans produce a brain with about 100,000,000,000 neurons, which communicate with one another at about 100,000,000,000,000 interaction sites termed *synapses*.

Genomics — the study of the entire DNA sequences of organisms — has shown us how close humans really are to Neanderthals and to our nearest nonhominid relatives, the great apes (Figure 1-27). Human DNA is 99 percent identical in sequence to that of chimpanzees and bonobos; the 1 percent difference is about 3,000,000 base pairs, but it somehow explains the obvious differences between our species, such as the evolution of human brains during the past ~5,000,000 years since we last shared a common ancestor.

FIGURE 1-27 Evolutionary tree connecting monkeys, apes, and humans. This evolutionary tree of humans, Neanderthals, great apes, a small ape, and an Old World monkey was

estimated from the divergence among their genomic DNA sequences. Whole-genome DNA sequences were aligned, and the average nucleotide divergence in unique DNA sequences was estimated. Estimates of the times the different species diverged from each other, indicated at each node, were calculated in millions of years (Myr) based on DNA sequence identity; $\sim 1\ \mathrm{Myr}$ implies approximately $1\ \mathrm{Myr}$ or less.

[Data from D. P. Locke et al., 2011, *Nature* **469**:529–533 and K. Prüfer et al., 2014, *Nature* **505**:43.]

Genomics coupled with paleontological findings indicates that humans and mice descended from a common mammalian ancestor that probably lived about 75 million years ago. Nonetheless, both organisms contain about the same number of genes, and about 99 percent of mouse protein-coding genes have homologs in humans, and vice versa. Over 90 percent of mouse and human genomes can be partitioned into regions of **synteny** — that is, DNA segments that have the same order of unique DNA sequences and genes along a segment of a chromosome. This observation suggests that much of the gene order in the most recent common ancestor of humans and mice has been conserved in both species (Figure 1-28). Of course, mice are not people; relative to humans, mice have expanded families of genes related to immunity, reproduction, and olfaction, probably reflecting the differences between the human and mouse lifestyles.

FIGURE 1-28 Conservation of synteny between human and mouse. Shown is a 510,000-base-pair (bp) segment of mouse chromosome 12 that shares common ancestry with a 600,000-bp section of human chromosome 14. Pink lines connect the conserved unique DNA sequences in the two genomes. Mb, 1 million base pairs.

[Data from Mouse Genome Sequencing Consortium, 2002, *Nature* **420**:520.]

It's not only human evolution that interests us! Polar bears live in the Arctic and eat a high-fat diet, mostly composed of seals. Recent genome sequencing allowed researchers to conclude that the most recent common ancestor of polar bears and their brown bear relatives, which live in temperate climates, was present about 500,000 years — or only about 20,000 bear generations — ago. During that rather short evolutionary period the polar bear genome acquired changes in many genes regulating cardiovascular function, fat metabolism, and heart development, allowing it to consume a diet very rich in fats.

Development Uses a Conserved Set of Master Transcription Factors and Involves Epigenetic Modifications to

DNA and Its Associated Histone Proteins

The astute reader will note a paradox in the previous discussion: if indeed most human protein-coding genes are shared with apes and mice, and many with flies and worms, how is it that these organisms look and function so differently? The answer to this question resides in the way genes are regulated during the development of all metazoans from a single cell, the fertilized egg. As we learn in Chapters 7 and 8, each protein-coding gene is associated with regulatory DNA sequences that differ in different organisms. Many of these regulatory sequences bind proteins that direct the expression of the gene, and thus the amount of a protein it makes, in specific types of cells. Some of these proteins are termed *master transcription factors*; these proteins bind to regulatory DNA sequences, are conserved throughout evolution, and control the development of specific types of cells by activating or repressing groups of genes, often at different or successive stages of development.

During development, many segments of each chromosome undergo enzyme-catalyzed chemical modifications — termed **epigenetic modifications** — that affect the ability of genes within these segments to be transcribed into RNA. As one example, addition of methyl (CH_3) groups to multiple cytosine bases in a segment of DNA triggers the formation of heterochromatin — condensed,

concentrated DNA that cannot be transcribed into RNA. Histone proteins bound to DNA can undergo multiple kinds of enzyme-catalyzed modifications, some enhancing and others inhibiting the ability of RNA polymerase to transcribe the adjacent gene into RNA. As detailed in Chapter 8, many of these modifications are replicated and passed on to daughter cells, a type of cell heredity that does not involve changes in the primary nucleotide sequence of the DNA genome.

The early stages in the development of a human embryo are similar to those in the mouse. They are characterized by rapid cell divisions (Figure 1-29) followed by the differentiation of cells into tissues. In all organisms, the embryonic body plan — the spatial pattern of cell types (tissues) and body parts — emerges from two influences: a program of genes that specifies the pattern of the body, and local cell interactions that induce different parts of the program.

FIGURE 1-29 The first few cell divisions of a fertilized egg set the stage for all subsequent development. A developing mouse embryo is shown at the (a) two-cell, (b) four-cell, and (c) eight-cell stages. The embryo is surrounded by supporting membranes. The corresponding steps in human development occur during the first few days after fertilization.

With only a few exceptions, animals display axial symmetry; that is, their left and right sides mirror each other. This most basic of patterns is encoded in the genome. Developmental biologists have divided bilaterally symmetric animal phyla into two large groups depending on where the mouth and anus form in the early embryo. **Protostomes** develop a mouth close to a transient opening in the early embryo (the **blastopore**) and have a ventral nerve cord; protostomes include all worms, insects, and mollusks. **Deuterostomes** develop an anus close to this transient opening in the embryo and have a dorsal central nervous system; they include echinoderms (such as sea stars and sea urchins) and vertebrates. The bodies of both protostomes and deuterostomes are divided into discrete segments that form early in embryonic development. Protostomes and deuterostomes probably evolved from a common ancestor, termed *Urbilateria*, that lived approximately 600 million years ago (Figure 1-30a).

FIGURE 1-30 Similar master transcription factors, conserved during evolution, regulate early developmental processes in diverse animals. (a) Urbilateria is the presumed ancestor of all protostomes and deuterostomes that existed about 600 million years ago. The positions of its nerve cord (violet), surface ectoderm (mainly skin; white), and endoderm (mainly digestive tract and internal organs; light green) are shown. (b) Highly conserved master transcription factors called Hox proteins, which determine the identity of body segments during embryonic development, are found in both protostomes and deuterostomes. Hox genes are found in clusters on the chromosomes of most or all animals,

and they encode related master transcription factors that control the activities of other genes. In many animals, different Hox genes direct the development of different segments along the head-to-tail axis, as indicated by corresponding colors. Each Hox gene is activated (transcriptionally) in a specific region along the head-to-tail axis and controls the growth and development of tissues in that segment. For example, in the mouse, a deuterostome, certain Hox genes are responsible for the distinctive shapes of vertebrae. Mutations affecting Hox genes in the fruit fly, a protostome, cause body parts to form in the wrong locations, such as legs in lieu of antennae on the head. In both organisms, these genes provide a head-to-tail address and serve to direct the formation of structures in the appropriate places.

Many **patterning genes** encode master transcription factors that control expression of other genes and specify the general organization of an organism, beginning with the major body axes — anterior-posterior (head-to-tail), dorsal-ventral (back-to-belly), and left-right — and ending with body segments such as the head, chest, abdomen, and tail. The conservation of axial symmetry from the simplest worms to mammals is explained by the presence of conserved patterning genes in their genomes. Other patterning genes encode proteins that are important in cell adhesion or in cell signaling. This broad repertoire of patterning genes permits the integration and coordination of events in different parts of the developing embryo and gives each segment in the body its unique identity.

Remarkably, many patterning genes encoding master transcription factors are highly conserved in both protostomes and deuterostomes (Figure 1-30b). This conservation of body plan reflects evolutionary pressure to preserve the commonalities in the

molecular and cellular mechanisms controlling development in different organisms.

1.6 Metazoan Organisms Widely Used in Cell Biology Research

Many invertebrate and vertebrate organisms have been and continue to be immensely valuable for cell biology research. Invertebrate organisms with large-celled embryos that develop outside the mother's body (e.g., sea urchins and sea stars) are extremely useful for tracing the fates of cells as they form different tissues, as well as for making extracts for biochemical studies. For instance, a key protein in regulating cell division in all eukaryotes, including humans, was first identified in studies with sea star and sea urchin embryos and subsequently purified from extracts prepared from these embryos (see Chapter 19). Other organisms are investigated because of their adaptation to specific ecological niches. An example is the tardigrades, tiny 0.5-mm-long, 8-legged invertebrates (see the photo on the first page of the chapter). Tardigrades are widely studied because of their ability to survive exposures to extreme temperatures, high and low pressures, dehydration, and starvation. Indeed, they are the only organisms known to survive exposure to the deadly combination of low pressure and intense radiation of outer space.

A few invertebrates — notably the roundworm *Caenorhabditis elegans*, the fruit fly *Drosophila melanogaster*, and the planarian *Schmidtea mediterranea* — are especially amenable to a variety of

experimental approaches. These invertebrates have been extensively studied by thousands of research groups using multiple experimental technologies. Studies on these and other invertebrates led to important insights into animal development and cell function, and also to understanding of many human diseases.

Drosophila melanogaster and *Caenorhabditis elegans* Are Used to Identify Genes That Regulate Animal Development

D. melanogaster has been used as an experimental organism since 1910, when Thomas Hunt Morgan established the Fly Room laboratory at Columbia University. It is still extensively used in research because it can be readily reared in the laboratory, has only four pairs of chromosomes, breeds quickly, and lays many eggs (see Figure 1-23d). Each step in the development of this organism — from fertilized egg through the embryonic larval and pupal stages to the mature adult — is well understood. Most importantly, mutations in many genes important for development have been characterized in detail and these have provided important information about the functions of the encoded proteins. As an example, many genes important for development of the *Drosophila* eye have been identified; one of them, *eyeless*, is the master transcription factor that initiates eye development. Fly eyes and human eyes are very

different in their structure, function, and nerve connections. Nonetheless, *eyeless* in the fly and *Pax6* in the human are highly related proteins that regulate the activities of other genes and are descended from the same ancestral gene. Mutations in both the *eyeless* and the *Pax6* genes cause major defects in eye formation (Figure 1-31).

FIGURE 1-31 Homologous genes regulate eye development in *Drosophila* and humans. (a) Development of the large compound eyes in fruit flies requires a gene called *eyeless* (named for the mutant phenotype). (b) Flies with inactivated *eyeless*

genes lack eyes. (c) Normal human eyes require the gene *Pax6*, the homolog of *eyeless*. (d) People lacking adequate *Pax6* function have the genetic disease *aniridia*, a lack of irises in the eyes. *Eyeless* and *Pax6*, which encode highly related master transcription factors that regulate the activities of other genes, are homologs and presumably descended from the same ancestral gene.

The roundworm *Caenorhabditis elegans* was developed as an experimental organism by Sydney Brenner only in the 1960s. The adult worm (see Figure 1-23c) — about 1 mm long and 70 μm in diameter — can be either a hermaphrodite (a worm with both male and female organs that can fertilize itself and produce viable offspring) or a male (which can fertilize a hermaphrodite); this unusual reproductive behavior has many advantages for the rapid isolation and characterization of mutations affecting development or cell function. The hermaphrodite has precisely 959 somatic (non-germ) cells, whereas the male has 1031 (see Figure 22-26d). These small numbers of cells are arranged in a nearly identical way in every worm, and scientists have traced the lineage of each somatic cell in *C. elegans* from the fertilized egg to the mature worm using microscopy to follow the development of live worms (see Figure 22-26c). As we learn in Chapter 22, many of the cells born during development of *C. elegans* are destined to die by a process termed **programmed cell death**, or **apoptosis**. A similar process utilizing similar proteins occurs in many human cells, and the absence of programmed cell death contributes to the development of many human cancers.

Planaria Are Used to Study Stem Cells and Tissue Regeneration

In single-celled organisms, both daughter cells usually (though not always) resemble the parent cell. Similarly, in multicellular organisms, when many types of cells divide, the daughter cells look a lot like the parent cell — liver cells, for instance, divide to generate liver cells with the same characteristics and functions as their parent, as do insulin-producing cells in the pancreas. In contrast, **stem cells** and certain other undifferentiated cells can generate multiple types of differentiated descendant cells; these cells often divide in such a way that the two daughter cells are different. Such **asymmetric cell division** is characteristic of stem cells and is critical to the generation of different cell types in the body (see Chapter 22). Often one daughter cell resembles its parent in that it remains undifferentiated and retains its ability to give rise to multiple types of differentiated cells. The other daughter cell divides many times, and each of its daughter cells differentiates into one or several specific types of cells.

The planarian *Schmidtea mediterranea* is best known for its capacity to regenerate complete individuals — with a normal head — from minuscule body parts formed by dissection (see Figure 1-23e). Planaria contain stem cells, termed *neoblasts*, that replace cells lost to normal turnover. In portions of a dissected animal, neoblasts will, after several cell divisions, generate any cell type needed during

regeneration. These stem cells have served as a potent experimental system to discover how heads and tails, each built of many types of cells, are formed (see Chapters 16 and 22). The hormones that instruct stem cells in different parts of the body to generate specific types of cells are similar to those used in mammals, including humans, in development (see Chapter 16), and thus future studies on planarian regeneration may inform scientists how to regenerate human body parts such as a hand or an eye.

Studies on Fish, Mice, and Other Vertebrate Organisms Inform the Study of Human Development and Disease

The zebrafish *Danio rerio* (see Figure 1-23f) is widely used to study the development and functions of organs not found in invertebrates, especially the brain and the central nervous system. Its generation time — from fertilized egg to daughter fertilized eggs — is only 3 months, short for a vertebrate. The fertilized egg rapidly becomes transparent, allowing visualization of developing organs, and the embryo develops rapidly, such that precursors to all major organs appear within 36 hours of fertilization.

Mice (see Figure 1-23g) have one enormous advantage over other experimental organisms: they are the most closely related to

humans of any animal for which powerful genetic approaches have been available for many years. Mice and humans have shared living structures for millennia, have similar nervous systems, have similar immune systems, and are subject to infection by many of the same pathogens. As noted, both organisms contain about the same number of genes, and about 99 percent of mouse protein-coding genes have homologs in the human genome, and vice versa.

Using the Cas9 and other experimental systems described in Chapter 6, researchers can inactivate any desired gene and thus abolish production of its encoded protein. This approach is being used extensively to produce animal versions of human genetic diseases, in mice as well as in other animals. As an example, people with autism spectrum disorder often have mutations in specific protein-coding genes that regulate development of specific types of nerve cells. To understand the role of these mutations, these genes have been inactivated in mice and more recently in macaque monkeys. These animals often exhibit symptoms of the human disease, including repetitive actions such as excessive grooming, strongly suggesting that the human mutation indeed has a role in triggering the disorder. Such approaches can be useful in uncovering the role of specific genes in higher order brain tasks such as learning and memory, or in studies of viruses that infect only humans and nonhuman primates. Once animal models of a human disease are available, investigators can perform further studies on the molecular defects causing the disease and can test

new treatments, thereby minimizing the testing of new drugs on humans.

Human Genetic Diseases Elucidate Important Aspects of Cell Function

We have emphasized how analysis of mutant organisms missing a specific protein has informed the normal function of that gene and encoded protein. Although we cannot induce mutations in humans as we might in other organisms, we can study naturally occurring mutations in humans. Many genetic diseases are caused by mutations in a single protein; thus studies on humans with these diseases also can shed light on the normal function of those proteins. As an example, consider Duchenne muscular dystrophy (DMD), the most common of the hereditary muscle-wasting diseases, collectively called *muscular dystrophies*. DMD is a disorder caused by mutations in the dystrophin gene localized on the X chromosome. It affects 1 in 3300 boys and results in cardiac or respiratory failure and death, usually in the late teens or early twenties.

The first clue to understanding the molecular basis of this disease came from the cloning of the dystrophin gene. As detailed in Chapters 17 and 20, the very large protein encoded by this gene binds to other proteins in muscle cells to form a large multiprotein

complex. One end of the long dystrophin molecule binds to actin microfilaments that are a component of the contractile apparatus (see Figure 1-14); the other binds to a complex of proteins in the muscle plasma membrane (see Figure 20-41). The resulting large multiprotein assemblage, the dystrophin glycoprotein complex (DGC), links the extracellular matrix protein laminin to the cytoskeleton within muscle cells and prevents the muscle cell from ripping apart during contractions. Mutations in dystrophin or other DGC components can disrupt the DGC-mediated link between the exterior and interior of muscle cells and cause muscle weakness and eventual muscle deterioration and death. The first step in identifying the entire dystrophin glycoprotein complex was to clone the dystrophin-encoding gene using DNA from normal individuals and from patients with Duchenne.

Unbiased Single Cell Sequencing Experiments Identify Altogether New Cell Types

How many different types of cells make up a mouse or a human body? Certain types of cells may carry out very important functions, but because they are present in miniscule amounts in a specific organ or tissue their very existence may have gone unnoticed!

The new technique of single cell RNA sequencing (Chapter 6) allows researchers to identify cell types present in only small amounts. The technique identifies the ~5000 types of messenger RNAs that are expressed in the largest numbers in a single isolated cell. If researchers apply the technique to many individual cells isolated from a tissue, they can identify new types of cells whose components of messenger RNAs, and thus of the proteins they encode, are different from those of known types of cells.

In a recent study using single-cell RNA sequencing, researchers analyzed tens of thousands of cells from mouse and human airways, mapping the physical locations of cell types and creating a cellular atlas of the tissue. Using a computer program to analyze the overall similarity between the types of mRNAs expressed in each cell, the researchers easily found six groups of cells that each expressed a similar population of mRNAs. These six groups of cells corresponded to the six well-known cell types present in the trachea — the abundant basal, club, and ciliated cells and the rarer tuft, neuroendocrine, and goblet cells. One extremely rare cell type, making up roughly 1 percent of the cell population, had a profile of mRNAs radically different from the 6 other known cells. The team named this new cell the *pulmonary ionocyte*. Strikingly, pulmonary ionocytes were found to express the *CFTR* gene at levels higher than any other cell type. The CFTR protein is critical for airway function; mutations in the *CFTR* gene cause cystic fibrosis in humans. For decades, researchers and clinicians assumed that the *CFTR* gene is

frequently expressed at low levels in ciliated cells, a cell type spread throughout the entire airway. According to the new data, the majority of CFTR is expressed in only a few cells (Figure 1-32), which researchers didn't even know existed until now.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 1-32 A new cell type in the mouse airway identified by unbiased single-cell sequencing of messenger RNAs. Ionocytes, a minor cell type in the upper respiratory tract of the mouse that express the CFTR protein, are stained green with an antibody that detects a protein expressed only in these cells. All cell nuclei are stained with a blue dye. By counting the number of blue nuclei in the tissue section, it can be determined that ionocytes comprise about 1 percent of the cells lining the mouse trachea (airway). These cells extend through the layer of neighboring epithelial cells to the airway surface. See text for an explanation of how these cells were identified.

The Following Chapters Present Many Experimental Techniques and Much Experimental Data That Explains How We Know What We Know About Cell Structure and Function

In subsequent chapters of this book, we discuss cellular processes in much greater detail. We begin (in Chapter 2) with a discussion of the chemical nature of the building blocks of cells and the basic chemical processes required to understand the macromolecular processes discussed in subsequent chapters. We go on to discuss the structure and function of proteins (in Chapter 3). Chapter 4 discusses many of the techniques biologists use to culture and fractionate cells and to visualize specific proteins and structures within cells. Chapter 5 describes how DNA is replicated, how segments of DNA are copied into RNA, and how proteins are synthesized on ribosomes. Chapter 6 describes many of the techniques used to study genes, gene expression, and protein function, including the generation of animals with specific genetic mutations. Gene and chromosome structure and the regulation of gene expression are covered in Chapters 7, 8, and 9. Biomembrane structure is the topic of Chapter 10. The transport of ions and small

molecules across membranes is covered in Chapter 11, and Chapter 12 discusses cellular energetics and the functions of mitochondria and chloroplasts. Membrane biogenesis, protein secretion, and protein trafficking — the directing of proteins to their correct subcellular destinations — are the topics of Chapters 13 and 14. Chapters 15 and 16 discuss the many types of signals and signal receptors used by cells to communicate and regulate their activities. The cytoskeleton and cell movements are discussed in Chapters 17 and 18. Chapter 19 discusses the cell cycle and how cell division is regulated. The interactions among cells, and between cells and the extracellular matrix, that enable formation of tissues and organs are detailed in Chapter 20. A chapter new to this edition, Chapter 21, details how cells respond to changes in their environment — specifically, to changes in oxygen levels, temperature, day and night, and nutrient levels. Later chapters of the book discuss important types of specialized cells — stem cells (Chapter 22), neurons (Chapter 23), and cells of the immune system (Chapter 24). Chapter 25 discusses cancer and the multiple ways in which cell growth and differentiation can be altered by mutations.

CHAPTER 2

Chemical Foundations

Dr. Robert Krickl

Model of sodium chloride (NaCl) crystal. This photograph shows the largest (3.1 m tall) ball-and-stick physical model of a crystalline salt ever constructed, built from 40,110 balls by Robert Krickl.

OUTLINE

2.1 Covalent Bonds and Noncovalent Interactions
2.2 Chemical Building Blocks of Cells
2.3 Chemical Reactions and Chemical Equilibrium
2.4 Biochemical Energetics

The life of a cell depends on thousands of chemical interactions and reactions exquisitely coordinated with one another in time and space, influenced by the cell's genetic instructions and its environment. By understanding these interactions and reactions at a molecular level, we can begin to answer fundamental questions about cellular life: How does a cell extract nutrients and information from its environment? How does a cell convert the energy stored in nutrients into the work of movement or metabolism? How does a cell transform nutrients into the cellular components required for its survival? How does a cell transmit its genetic information to its progeny and use this information to survive and thrive? How does a cell link itself to other cells to form a tissue? How do cells communicate with one another so that a complex, efficiently functioning organism can develop and thrive? One of the goals of this textbook is to answer these and other questions about the structure and function of cells and organisms in terms of the properties of individual molecules and ions.

For example, the properties of one such molecule, water, control the evolution, structure, and function of all cells. An understanding of

biology is not possible without appreciating how the properties of water control the chemistry of life. Life first arose in a watery environment, and water constitutes 70–80 percent of most cells by weight. In fact, water is the most abundant molecule in biological systems. The remaining mass of organisms is made up of small molecules and ions and of combinations of these that form the larger macromolecules and macromolecular assemblies that make up a cell's machinery and architecture. The small molecules typically have molecular weights of less than 1000 daltons and include amino acids (the building blocks of proteins), nucleotides (the building blocks of DNA and RNA), lipids (the building blocks of biomembranes), and sugars (the building blocks of complex carbohydrates). The small molecules and ions together make up about 7 percent of the weight of living matter.

Many of the cell's biomolecules (such as sugars) readily dissolve in water; these molecules are referred to as **hydrophilic** ("water liking"). Others (such as cholesterol) are oily, fatlike substances that shun water; these molecules are said to be **hydrophobic** ("water fearing"). Still other biomolecules (such as phospholipids) contain both hydrophilic and hydrophobic regions; these molecules are said to be **amphipathic or amphiphilic** ("both liking"). The smooth functioning of cells, tissues, and organisms depends on all these molecules, from the smallest to the largest. Indeed, the chemistry of the simple proton (H^+) can be as important to the survival of a human cell as that of each gigantic DNA molecule (the mass of the

DNA molecule in human chromosome 1 is 8.6×10^{10} times that of a proton!). The chemical interactions of all these molecules, large and small, with water and with one another define the nature of life.

Luckily, although many types of biomolecules interact and react in numerous and complex pathways to form functional cells and organisms, a relatively small number of chemical principles are necessary to understand cellular processes at the molecular level (Figure 2-1).

FIGURE 2-1 Chemistry of life: four key concepts. (a) Molecular complementarity lies at the heart of all biomolecular interactions (see Section 2.1), as when two proteins with complementary shapes and chemical properties come together to form a tightly bound complex. (b) Small molecules serve as building blocks for larger structures (see Section 2.2). For example, to generate the information-carrying macromolecule DNA, four small nucleotide building blocks are covalently linked into long strings (polymers), which then

wrap around each other to form the double helix. (c) Chemical reactions are reversible, and the distribution of the chemicals between starting reactants (*left*) and the products of the reactions (*right*) depends on the rate constants of the forward (k_{f}, upper arrow) and reverse (k_{r}, lower arrow) reactions. The ratio of these, K_{eq}, provides an informative measure of the relative amounts of products and reactants that will be present at equilibrium (see Section 2.3). (d) In many cases, the source of energy for chemical reactions in cells is the hydrolysis of the molecule ATP (see Section 2.4). This energy is released when a high-energy phosphoanhydride bond linking the β and γ phosphates in the ATP molecule (red) is broken by the addition of a water molecule, forming ADP and $\mathrm{P_i}$.

First, biological molecules are able to bind together where their surfaces have complementary shapes and chemical properties — negatively charged surfaces with positively charged surfaces, for example (Figure 2-1a). Second, as we have seen, chemical building blocks assemble to form macromolecules (Figure 2-1b). Third, these assemblages are possible because molecules are able to react to form new products in chemical reactions, which can proceed to chemical equilibrium (Figure 2-1c) or steady state. Finally, molecules release the energy stored in chemical bonds in a controlled fashion to power the work of the cell (Figure 2-1d). In this chapter, we review these key principles, some of which you already know well, because a little bit of chemistry can go a very long way in helping us to understand molecular cell biology. We begin with the covalent bonds that connect atoms into molecules and the noncovalent interactions that stabilize groups of atoms within and between molecules. We then consider the basic chemical building blocks of macromolecules and macromolecular assemblies. After reviewing those aspects of chemical equilibrium that are most

relevant to biological systems, we end the chapter with the basic principles of biochemical energetics, including the central role of ATP (adenosine triphosphate) in capturing and transferring energy in cellular metabolism.

2.1 Covalent Bonds and Noncovalent Interactions

Underpinning all of biology is the assembly of atoms into molecules that in turn interact with one another. Strong and weak attractive forces between atoms are the glue that holds individual molecules together and permits interactions between different molecules. When two atoms share a single pair of electrons, the result is a **covalent bond** — a type of strong force that links atoms together in molecules. When two atoms share multiple pairs of electrons, the result is multiple covalent bonds (e.g., double or triple bonds). The weak attractive forces of **noncovalent interactions** are equally important in determining the properties and functions of biomolecules such as proteins, nucleic acids, carbohydrates, and lipids. In this section, we first review covalent bonds and then discuss the four major types of noncovalent interactions: ionic bonds, hydrogen bonds, van der Waals interactions, and the hydrophobic effect.

The Electronic Structure of an Atom Determines the Number and Geometry of the Covalent Bonds It Can Make

Hydrogen, oxygen, carbon, nitrogen, phosphorus, and sulfur are the most abundant elements in biological molecules. These atoms, which rarely exist as isolated entities, readily form covalent bonds, sharing electrons in the outermost electron orbitals surrounding their nuclei (Figure 2-2). As a rule, each type of atom forms a characteristic number of covalent bonds with other atoms. These bonds have a well-defined geometry determined by the atom's size and by both the distribution of electrons around the nucleus and the number of electrons it can share. In some cases, the number of stable covalent bonds an atom can make is fixed; carbon, for example, always forms four covalent bonds. In other cases, the number of stable covalent bonds can vary; for example, sulfur can form two, four, or six stable covalent bonds.

FIGURE 2-2 Covalent bonds form by the sharing of electrons. Covalent bonds, the strong forces that hold atoms together in molecules, form when atoms share electrons from their outermost electron orbitals. Each atom forms a defined number of covalent bonds having a distinct geometry.

All the biological building blocks are organized around the carbon atom. In these organic biomolecules, each carbon usually bonds to three or four other atoms. [Carbon can also bond to two other atoms, as in the linear molecule carbon dioxide, CO_2, which has two carbon-oxygen double bonds (O=C=O); however, such bond arrangements of carbon are not found in biological building blocks.] As illustrated in Figure 2-3a for formaldehyde, carbon can bond to three atoms, all in a common plane. The carbon atom forms two single bonds with two atoms and one double bond (two shared electron pairs) with the third atom. In the absence of other constraints, atoms joined by a single bond generally can rotate freely about the bond axis, whereas those connected by a double bond cannot. The rigid planarity imposed by double bonds has enormous significance for the shapes and flexibility of biomolecules such as phospholipids, proteins, and nucleic acids.

FIGURE 2-3 Geometry of bonds when carbon is covalently linked to three or four other atoms. (a) A carbon atom can be bonded to three atoms, as in formaldehyde (CH_2O). In this case, the carbon-bonding electrons participate in two single bonds and one double bond. All bonds lie in the same plane. Unlike atoms connected by a single bond, which usually can rotate freely about the bond axis, those connected by a double bond cannot. (b) When a carbon atom forms four single bonds, as in methane (CH_4), the bonded atoms (all H in this case) are oriented in space in the form of a tetrahedron. The letter representations on the left clearly indicate the atomic composition of each molecule and its bonding pattern. The ball-and-stick models in the center illustrate the geometric arrangement of the atoms and bonds, but the diameters of the balls representing the atoms and their nonbonding electrons are unrealistically small compared with the bond lengths. The sizes of the electron clouds in the space-filling models on the right more accurately represent the structure in three dimensions.

Carbon can also bond to four rather than three atoms. As illustrated by methane (CH_4), when carbon is bonded to four other atoms, the angle between any two bonds is 109.5°, and the positions of bonded atoms define the four points of a tetrahedron (Figure 2-3b). This geometry defines the structures of many biomolecules. A carbon (or any other) atom bonded to four dissimilar atoms or groups in a nonplanar configuration is said to be asymmetric. The four atoms connected to an *asymmetric carbon atom* in a tetrahedral orientation can be arranged in three-dimensional space in two different ways, producing molecules that are mirror images of each other, a property called *chirality* ("handedness," from the Greek word *cheir*, meaning "hand") (Figure 2-4). Such molecules are called *optical isomers*, or **stereoisomers**. Many molecules in cells contain at least one asymmetric carbon atom, often called a *chiral carbon* atom. The different stereoisomers of a molecule usually have completely different biological activities because the arrangement of atoms within their structures, and thus their ability to interact with other molecules, differs.

FIGURE 2-4 Stereoisomers. Many molecules in cells contain at least one asymmetric carbon atom. The tetrahedral geometry of bonds formed by an asymmetric carbon atom can be arranged in three-dimensional space in two different ways, producing molecules that are mirror images, or stereoisomers, of each other. Shown here is the common structure of an amino acid, with its central asymmetric carbon and four attached groups, including the R group, discussed in Section 2.2. Amino acids can exist in two mirror-image forms, designated L and D. Although the chemical properties of such stereoisomers are identical, their biological activities are distinct. Only L amino acids are found in proteins.

Some drugs are mixtures of the stereoisomers of a small molecule in which only one stereoisomer has the biological activity of interest, for example, inhibiting the activity of a specific protein molecule. Unfortunately, both the stereoisomer that has the biological activity of interest and the one without biological activity might have side effects that could be harmful. The use of a pure,

single stereoisomer of the chemical in place of the mixture may result in a more potent drug with fewer side effects. For example, one stereoisomer of the antidepressant drug *citalopram* (Celexa) is 170 times more potent than the other. Some stereoisomers have very different activities. Darvon is a pain reliever, whereas its stereoisomer, Novrad (*Darvon* spelled backward), is a cough suppressant. One stereoisomer of ketamine is an anesthetic, whereas the other causes hallucinations. ■

The typical numbers of covalent bonds formed by atoms common in biomolecules are shown in Table 2-1. A hydrogen atom forms only one covalent bond. An oxygen atom usually forms only two covalent bonds but has two additional pairs of electrons (indicated as dots in the table) that can participate in noncovalent interactions. These extra electrons that are not shared in a covalent bond are also called *nonbonding* electrons. As we will see in later chapters, the nonbonding electrons can play important roles in the chemical reactions between biomolecules. A sulfur atom forms two covalent bonds in hydrogen sulfide (H_2S) but can accommodate six covalent bonds in sulfuric acid (H_2SO_4) and its sulfate derivatives. Nitrogen and phosphorus atoms each have five electrons to share. In ammonia (NH_3), the nitrogen atom forms three covalent bonds; the pair of electrons around the atom not involved in a covalent bond can take part in noncovalent interactions. In the ammonium ion (NH_4^+), the nitrogen atom forms four covalent bonds, which have a tetrahedral geometry. A phosphorus atom commonly forms five

covalent bonds, as in phosphoric acid (H_3PO_4) and its phosphate derivatives, which form the backbone of nucleic acids. Phosphate groups covalently attached to proteins play a key role in regulating the activity of many proteins, and the central molecule in cellular energetics, ATP, contains three phosphate groups (see Section 2.4). A summary of common covalent linkages and functional groups, which confer distinctive chemical properties on the molecules of which they are a part, is provided in Table 2-2.

TABLE 2-1 • Bonding Properties of Atoms Most Abundant in Biomolecules

Atom and Outer Electrons	Usual Number of Covalent Bonds	Typical Bond Geometry
H	1	H
O	2	O
S	2, 4, or 6	S
N	3 or 4	N
P	5	P
C	4	C

TABLE 2-2 • Common Functional Groups and Linkages in Biomolecules

Functional Groups			
—OH Hydroxyl (alcohol)	O ‖ —C—R Acyl (triacylglycerol)	O ‖ —C— Carbonyl (ketone)	O ‖ —C—O⁻ Carboxyl (carboxylic acid)
—SH Sulfhydryl (thiol)	$-NH_2$ or $-\overset{+}{N}H_3$ Amino (amine)	O ‖ —O—P—O⁻ | O⁻ Phosphate (phosphorylated molecule)	O O ‖ ‖ ⁻O—P—O—P—O⁻ | | OH OH Pyrophosphate (diphosphate)
Linkages			
O ‖ —C—O—C— Ester		—C—O—C— Ether	O ‖ —N—C— Amide

All Covalent Bonds Are Not Equal: Electrons May Be Shared Equally or Unequally in Covalent Bonds

The extent of an atom's ability to attract an electron is called its *electronegativity*. In a bond between atoms with identical or similar electronegativities, the bonding electrons are essentially shared equally between the two atoms, as is the case for most carbon-carbon single bonds (C—C) and carbon-hydrogen single bonds (C—H). Such bonds are called **nonpolar**. In many molecules, however, the covalently bonded atoms sharing electrons have different electronegativities, resulting in unequal sharing of electrons. The bond between atoms that share electrons unequally is said to be **polar**.

One end of a polar bond has a partial negative charge (δ^-), and the other end has a partial positive charge (δ^+). In an O–H bond, for example, the oxygen atom is more electronegative than the hydrogen atom. As a result, the electrons forming the covalent bond spend more time around the oxygen atom than around the hydrogen. Thus the O–H bond possesses an electric **dipole**, a positive charge separated from an equal but opposite negative charge. The amount of δ^- charge on the oxygen atom of an O–H dipole is approximately 25 percent that of an electron, and there is an equivalent and opposite δ^+ charge on the H atom.

A common quantitative measure of the extent of charge separation, or strength, of a dipole is called the **dipole moment**, μ. For a chemical bond, the dipole moment is the product of the partial charge on each atom and the distance between the two atoms. Many molecules have multiple dipoles. In these cases, the amount of charge separation for the molecule as a whole — the molecule's dipole moment — depends in part on the dipole moments of all of its individual chemical bonds and in part on the geometry of the molecule (the relative orientations of the individual bond dipole moments).

Consider the example of water (H_2O). A water molecule has two O–H bonds and thus two individual bond dipole moments. If water were a linear molecule with the two bonds on exact opposite sides of the O atom, the two dipoles on each end of the molecule would be

identical in strength but would be oriented in opposite directions. The two dipole moments would cancel each other, and the dipole moment of the molecule as a whole would be zero. However, water is a V-shaped molecule, with the individual dipoles of its two O—H bonds both pointing toward the oxygen. One end of the water molecule (the end with the oxygen atom) has a partial negative charge and the other end (the one with the two hydrogen atoms) has a partial positive charge. As a consequence, the molecule as a whole is a dipole with a well-defined dipole moment (Figure 2-5). This dipole moment and the electronic properties of the oxygen and hydrogen atoms allow water to form electrostatic, noncovalent interactions with other water molecules and with molecules of other types. These interactions play a critical role in almost every biochemical interaction in cells and organisms, as we will see shortly.

FIGURE 2-5 The dipole nature of a water molecule. The symbol δ represents a partial charge (a weaker charge than the one on an electron or a proton). Because of the difference in the electronegativities of H and O, each of the polar H—O bonds in water is a dipole. The sizes and directions of the dipoles of each

of the bonds determine the net distance between charges and amount of charge separation in the molecule — its dipole moment.

Another important example of polarity is the O=P double bond in H_3PO_4. In the structure of H_3PO_4 shown on the top of the next page, lines represent single and double bonds and nonbonding electrons are shown as pairs of dots (each dot represents one electron):

Because of the polarity of the O=P double bond, H_3PO_4 can also be represented by the structure on the right, in which one of the electrons from the P=O double bond has accumulated around the O atom, giving it a negative charge and leaving the P atom with a positive charge. These charges are important in noncovalent interactions. Neither of these two models precisely describes the electronic state of H_3PO_4. The actual structure can be considered to be an intermediate, or hybrid, between these two representations, as indicated by the double-headed arrow between them. Such intermediate structures are called *resonance hybrids*.

Covalent Bonds Are Much Stronger and More Stable Than Noncovalent Interactions

Covalent bonds are considered to be strong because the energies required to break them are much greater than the thermal energy available at room temperature ($25\ ^\circ\mathrm{C}$) or body temperature ($37\ ^\circ\mathrm{C}$). As a consequence, covalent bonds are stable at these temperatures. For example, the thermal energy available at $25\ ^\circ\mathrm{C}$ is approximately 0.6 kilocalorie per mole ($\mathrm{kcal/mol}$), whereas the energy required to break the $\mathrm{C{-}C}$ bond in ethane is about 140 times larger (Figure 2-6). Consequently, at room temperature ($25\ ^\circ\mathrm{C}$), fewer than 1 in 10^{12} ethane molecules are broken into pairs of CH_3 molecules, each containing an unpaired, nonbonding electron (called a *radical*).

FIGURE 2-6 Relative energies of covalent bonds and noncovalent interactions. Bond energies are defined as the energy required to break a particular type of linkage. Shown here are the energies required to break a

variety of linkages, arranged on a log scale. Covalent bonds, including single (C−C) and double (C=C) carbon-carbon bonds, are one to two powers of 10 stronger than noncovalent interactions. Noncovalent interactions have energies somewhat greater than the thermal energy of the environment at normal room temperature (25 °C). Many biological processes are coupled to the energy released during hydrolysis of a phosphoanhydride bond in ATP.

Covalent single bonds in biological molecules have energies similar to the energy of the C−C bond in ethane. Because more electrons are shared between atoms in double bonds, they require more energy to break than single bonds. For instance, it takes 84 kcal/mol to break a single C−O bond but 170 kcal/mol to break a C=O double bond. The most common double bonds in biological molecules are C=O, C=N, C=C, and P=O.

In contrast, the energy required to break noncovalent interactions is only 1−5 kcal/mol, much less than the bond energies of covalent bonds (see Figure 2-6). Indeed, noncovalent interactions are weak enough that they are constantly being formed and broken at room temperature. Although these weak interactions have a transient existence at physiological temperatures (25−37 °C), multiple noncovalent interactions can, as we will see, act together to produce highly stable and specific associations between different parts of a large molecule or between different macromolecules. Protein-protein and protein-nucleic acid interactions are good examples of such noncovalent interactions. Below, we review the four main

types of noncovalent interactions and then consider their roles in the binding of biomolecules to one another and to other molecules.

Ionic Bonds Are Noncovalent Interactions Formed by the Electrostatic Attractions Between Oppositely Charged Ions

Ionic bonds (also called *ionic interactions*) result from the attraction between a positively charged ion — a **cation** — and a negatively charged ion — an **anion**. In sodium chloride (NaCl), for example, the bonding electron contributed by the sodium atom is completely transferred to the chlorine atom (Figure 2-7a). Unlike covalent bonds, ionic interactions do not have fixed or specific geometric orientations because the electrostatic field around an ion — its attraction for an opposite charge — is uniform in all directions. In solid NaCl, oppositely charged ions pack tightly together in an alternating pattern, forming the highly ordered crystalline array, or lattice, that is typical of salt crystals (Figure 2-7b, and see the opening figure for this chapter). The energy required to break an ionic interaction depends on the distance between the ions and the electrical properties of the environment of the ions.

FIGURE 2-7 Electrostatic interactions of the oppositely charged ions of salt (NaCl) in crystals and in aqueous solution. (a) In crystalline table salt, sodium atoms are positively charged ions (Na^+) due to the loss of one electron each, whereas chloride atoms are correspondingly negatively charged (Cl^-) due to the gain of one electron each. (b) In solid form, ionic compounds form neatly ordered arrays, or crystals, of tightly packed ions in which the positively and negatively charged ions counterbalance each other. (c) When the crystals are dissolved in water, the ions separate, and their charges, no longer balanced by immediately adjacent ions of opposite charge, are stabilized by interactions with polar water. The water molecules and the ions are held together by electrostatic interactions between the charges on the ion and the partial charges on the water's oxygen and hydrogen atoms. In aqueous solutions, all ions are surrounded by a hydration shell of water molecules.

When solid salts dissolve in water, the ions separate from one another and are stabilized by their interactions with water molecules. In aqueous solutions, simple ions of biological significance, such as Na^+, K^+, Ca^{2+}, Mg^{2+}, and Cl^-, are *hydrated*, surrounded by a stable shell of water molecules held in place by electrostatic interactions between the ion at the center and the oppositely charged ends of the water molecules, which are dipoles (Figure 2-7c). Energy is released when ions tightly bind water molecules and spread out in an aqueous solution, due to the

increase in disorder, or entropy (see Section 2.4). Most ionic compounds dissolve readily in water because this energy of hydration is greater than the lattice energy that stabilizes the crystal structure. Parts or all of the aqueous *hydration shell* must be removed from ions in solution when they interact directly with proteins. For example, water of hydration is lost when ions pass through protein pores in the cell membrane during nerve conduction.

The relative strength of the interaction between two oppositely charged ions, A^- and C^+, depends on the concentration of other ions in a solution. The higher the concentration of other ions (e.g., Na^+ and Cl^-), the more opportunities A^- and C^+ have to interact ionically with those other ions, and thus the lower the energy required to break the interaction between A^- and C^+. As a result, increasing the concentrations of salts such as NaCl in a solution of biological molecules can weaken and even disrupt the ionic interactions holding the biomolecules together. This principle can be exploited to separate complex mixtures of interacting molecules, such as proteins, into their individual, pure components.

Hydrogen Bonds Are Noncovalent Interactions That Determine the

Properties of Water and the Water Solubility of Uncharged Molecules

A **hydrogen bond** is the interaction of a hydrogen atom with a partial positive charge in a dipole, such as water, with unpaired electrons from another atom, either in the same or in a different molecule. Normally, a hydrogen atom forms a covalent bond with a single other atom. However, a hydrogen atom covalently bonded to an electronegative donor atom D may form an additional weak association, the hydrogen bond, with an acceptor atom A, which must have a nonbonding pair of electrons available for the interaction:

$$D^{\delta-}\text{—}H^{\delta+} + : A^{\delta-} \rightleftharpoons D^{\delta-}\text{—}H^{\delta+} \underset{\textbf{Hydrogen bond}}{\cdot\!\square\!\cdot\!\square\!\cdot\!\square\!\cdot} : A^{\delta-}$$

The covalent D − H bond is a bit longer than it would be if there were no hydrogen bond because the acceptor pulls the hydrogen away from the donor. An important feature of all hydrogen bonds is directionality. In the strongest hydrogen bonds, the donor atom, the hydrogen atom, and the acceptor atom all lie in a straight line. Nonlinear hydrogen bonds are weaker than linear ones; still, multiple nonlinear hydrogen bonds help to stabilize the three-dimensional structures of many proteins.

Hydrogen bonds are both longer and weaker than covalent bonds between the same atoms. In water, for example, the distance between the nuclei of the hydrogen and oxygen atoms forming a hydrogen bond connecting two adjacent water molecules is about 0.27 nm, about twice the length of the covalent O–H bonds within a single water molecule (Figure 2-8a). A hydrogen bond between water molecules (approximately 5 kcal/mol) is much weaker than a covalent O–H bond (roughly 110 kcal/mol), although it is stronger than many other hydrogen bonds in biological molecules (1–2 kcal/mol). Extensive hydrogen bonding between water molecules accounts for many of water's key properties, including its unusually high melting and boiling points and its ability to dissolve many other molecules.

FIGURE 2-8 Hydrogen bonding of water with itself and with other compounds. Each pair of nonbonding outer electrons in an oxygen or a nitrogen atom can accept a hydrogen atom in a hydrogen bond. The hydroxyl and the amino groups can also form hydrogen bonds with water. (a) In liquid water, each water molecule forms transient hydrogen bonds with several others, creating a dynamic network of hydrogen-bonded molecules. (b) Water can also form hydrogen bonds with alcohols and amines, which accounts for the high solubility of these compounds. (c) The peptide group and the ester group, which are present in many biomolecules, commonly participate in hydrogen bonds with water or polar groups in other molecules.

The solubility of uncharged substances in an aqueous environment depends largely on their ability to form hydrogen bonds with water. For instance, the hydroxyl group (–OH) in alcohols (—CH_2OH) and the amino group (—NH_2) in amines (—CH_2NH_2) can form several hydrogen bonds with water, which allows these molecules to dissolve in water at high concentrations (Figure 2-8b). In general, molecules with polar bonds that easily form hydrogen bonds with water, as well as charged molecules and ions that interact with the dipole in water, can readily dissolve in water; that is, they are hydrophilic. In addition to hydroxyl and amino groups, many biological molecules contain peptide and ester groups, which form hydrogen bonds with water via otherwise nonbonded electrons on their carbonyl oxygens (Figure 2-8c). X-ray crystallography combined with computational analysis permits an accurate depiction of the distribution of the outermost unbonded electrons of atoms that can participate in hydrogen bonds as well as the electrons in covalent bonds, as illustrated in Figure 2-9.

FIGURE 2-9 Distribution of bonding and outer nonbonding electrons in the peptide group. Shown here is a peptide bond linking two amino acids within a protein called *crambin*. No protein has been structurally characterized at higher resolution than crambin. The black lines represent the covalent bonds between atoms. The red (negative) and blue (positive) lines represent contours of charge determined using x-ray crystallography and computational methods. The greater the number of contour lines, the higher the charge. The high density of red contour lines between atoms represents the covalent bonds (shared electron pairs). The two sets of red contour lines emanating from the oxygen (O) and not falling on a covalent bond (black line) represent the two pairs of nonbonding electrons on the oxygen that are available to participate in hydrogen bonding. The high density of blue contour lines near the hydrogen (H)

bonded to nitrogen (N) represents a partial positive charge, indicating that this H can participate in hydrogen bonding.

[From *Proc. Nat'l. Acad. Sci. USA*, 2000, **97**(7):3171–3176, Fig. 3A. Accurate protein crystallography at ultra-high resolution: Valence electron distribution in crambin, by Christian Jelsch et al., copyright (2000) National Academy of Sciences, USA.]

Van der Waals Interactions Are Weak Attractive Interactions Caused by Transient Dipoles

When any two atoms approach each other closely, they create a weak attractive force called a **van der Waals interaction**. These interactions result from the momentary random fluctuations in the distribution of the electrons of any atom. The random fluctuations give rise to a transient unequal distribution of electrons, creating a temporary dipole. If two noncovalently bonded atoms are close enough, electrons of one atom will perturb the electrons of the other. This perturbation generates a transient dipole in the second atom, and the two dipoles attract each other weakly (Figure 2-10). Similarly, a polar covalent bond in one molecule attracts an oppositely oriented dipole in another.

FIGURE 2-10 Two oxygen molecules in van der Waals contact. In this model, red indicates negative charge and blue indicates positive charge. Transient dipoles in the electron clouds of all atoms give rise to weak attractive forces, called *van der Waals interactions*. Each type of atom has a characteristic van der Waals radius at which van der Waals interactions with other atoms are optimal. Because atoms repel one another if they are close enough together for their outer electrons to overlap without being shared in a covalent bond, the van der Waals radius is a measure of the size of the electron cloud surrounding an atom. The covalent radius indicated here is for the double bond of O=O; the single-bond covalent radius of oxygen is slightly longer.

Van der Waals interactions, involving either transient or permanent dipoles, occur in all types of molecules, both polar and nonpolar. In particular, van der Waals interactions are responsible for the cohesion between nonpolar molecules such as heptane, $CH_3—(CH_2)_5—CH_3$, that cannot form hydrogen bonds or ionic interactions with each other. The strength of van der Waals interactions decreases rapidly with increasing distance; thus these noncovalent interactions can form only when atoms are quite close

to one another. However, if atoms get too close together, the negative charges of their electrons create a repulsive force. When the van der Waals attraction between two atoms exactly balances the repulsion between their two electron clouds, the atoms are said to be in van der Waals contact. The strength of the van der Waals interaction is about 1 kcal/mol, so it is weaker than typical hydrogen bonds, and its energy is only slightly higher than the average thermal energy of molecules at 25 °C. Thus multiple van der Waals interactions, a van der Waals interaction together with other noncovalent interactions, or both are required to form van der Waals–mediated, stable attractions within and between molecules.

The Hydrophobic Effect Causes Nonpolar Molecules to Adhere to One Another

Because nonpolar molecules do not contain charged groups, do not possess a dipole moment, and do not become hydrated, they are insoluble, or almost insoluble, in water; that is, they are hydrophobic. The covalent bonds between two carbon atoms and between carbon and hydrogen atoms are the most common nonpolar bonds in biological systems. **Hydrocarbons** — molecules made up only of carbon and hydrogen — are virtually insoluble in water. Large triacylglycerols (also known as triglycerides), which make up animal fats and vegetable oils, also essentially are insoluble

in water. As we will see later, the major part of these molecules consists of long hydrocarbon chains. After being shaken in water, triacylglycerols form a separate phase. A familiar example is the separation of oil from the water-based vinegar in an oil-and-vinegar salad dressing.

Nonpolar molecules or nonpolar parts of molecules tend to aggregate in water owing to a phenomenon called the **hydrophobic effect**. Because water molecules cannot form hydrogen bonds with nonpolar substances, they tend to form cages of relatively rigid hydrogen-bonded pentagons and hexagons around nonpolar molecules (Figure 2-11, *left*). This state is energetically unfavorable because it decreases the entropy, or randomness, of the population of water molecules. (The role of entropy in chemical systems is discussed in Section 2.4.) If nonpolar molecules in an aqueous environment aggregate with their hydrophobic surfaces facing each other, the net hydrophobic surface area exposed to water is reduced (Figure 2-11, *right*). As a consequence, fewer water molecules are needed to form the ordered cages surrounding the nonpolar molecules, entropy increases relative to the unaggregated state, and an energetically more favorable state is reached. In a sense, then, water squeezes the nonpolar molecules into aggregates. Rather than constituting an attractive force, as in hydrogen bonds, the hydrophobic effect results from an avoidance of an unstable state — that is, extensive water cages around individual nonpolar molecules.

FIGURE 2-11 Schematic depiction of the hydrophobic effect. Cages of water molecules form around nonpolar molecules in solution. These water molecules in cages are more ordered than water molecules in the surrounding bulk liquid. Aggregation of nonpolar molecules reduces the number of water molecules involved in forming highly ordered cages, resulting in a higher entropy, more energetically favorable state (*right*) compared with the unaggregated state (*left*).

Nonpolar molecules can also associate, albeit weakly, through van der Waals interactions. The net result of the hydrophobic effect and van der Waals interactions is a very powerful tendency for hydrophobic molecules in water to interact with one another, not with water molecules. Simply put, *like dissolves like*. Polar molecules

dissolve in polar solvents such as water; nonpolar molecules dissolve in nonpolar solvents such as hexane.

One well-known hydrophobic molecule is cholesterol (see Section 2.2). Cholesterol, triglycerides, and other poorly water-soluble molecules are called *lipids*. Unlike hydrophilic molecules such as glucose or amino acids, lipids cannot readily dissolve in the liquid portion of the blood, the aqueous circulatory system that transports molecules and cells throughout the body. Instead, lipids, such as cholesterol, must be packaged into special hydrophilic carriers, called *lipoproteins*, that can themselves dissolve in the blood and be transported throughout the body. There can be hundreds to thousands of lipid molecules packed into the center, or core, of each lipoprotein. The hydrophobic core is surrounded by amphipathic molecules that have hydrophilic parts that interact with water and hydrophobic parts that interact with one another and the core. The packaging of lipids into lipoproteins (discussed in Chapter 14) permits their efficient transport in blood and is reminiscent of the containerization of cargo for efficient, long-distance transport via cargo ships, trains, and trucks.

High-density lipoprotein (HDL) and low-density lipoprotein (LDL) are two such lipoprotein carriers. HDL is associated with reduced heart disease, and LDL with increased heart disease, and they are therefore often referred to as *good* and *bad* cholesterol, respectively. Actually, the cholesterol molecules and their derivatives that are

carried by both HDL and LDL are essentially identical and in themselves are neither good nor bad. However, HDL and LDL have different effects on cells. The bad cholesterol, LDL, contributes to clogging of the arteries (known as *atherosclerosis*) and consequent heart disease and stroke. The mechanisms linking HDL to reduced risk for heart attacks are unclear. ■

Molecular Complementarity Due to Noncovalent Interactions Leads to a Lock-and-Key Fit Between Biomolecules

Both inside and outside cells, ions and molecules constantly collide. The higher the concentration of any two types of molecules, the more likely they are to encounter each other. When two molecules do encounter each other, they are most likely to simply bounce apart because the noncovalent interactions that would bind them together are weak and have a transient existence at physiological temperatures. However, two distinct molecules can exhibit **molecular complementarity**, a lock-and-key kind of fit between their shapes, charges, or other physical properties. Two such structurally complementary molecules can form multiple noncovalent interactions at close range. When two such molecules bump into each other, these multiple interactions can result in their sticking together, or binding.

Figure 2-12 illustrates how a variety of multiple weak interactions can cause two hypothetical proteins to bind together tightly. Numerous examples of such protein-to-protein molecular complementarity may be found throughout this book (see, e.g., Figures 16-9 and 16-18b). Almost any other arrangement of the same groups of atoms on the two surfaces would not allow the molecules to bind so tightly. Such molecular complementarity between regions within a protein molecule allow it to fold into a unique three-dimensional shape (see Chapter 3); it is also what holds the two chains of DNA together in a double helix (see Chapter 5). Similar interactions underlie the association of groups of molecules into multimolecular assemblies, or complexes, leading to the formation of muscle fibers, to the gluelike associations between cells in solid tissues, and to numerous other cellular structures. The antibodies that help neutralize pathogens (see Chapter 24) bind to them using similar principles of complementary molecular shapes.

FIGURE 2-12 Molecular complementarity permits tight protein bonding via multiple noncovalent interactions. The complementary shapes, charges, polarity, and hydrophobicity of two protein surfaces permit multiple weak interactions, which in combination produce a strong interaction and tight binding. Because deviations from molecular complementarity substantially weaken binding, a particular surface region of any given biomolecule usually can bind tightly to only one or a very limited number of other molecules. The complementarity of the two protein molecules on the left permits them to bind much more tightly than the two noncomplementary proteins on the right.

Depending on the number and strength of the noncovalent interactions between the two molecules and on their environment, their binding may be tight or loose and, as a consequence, either lasting or transient. The higher the *affinity* of two molecules for each other, the better the molecular fit between them, the more noncovalent interactions can form, and the more tightly they can bind together. An important quantitative measure of affinity is the

binding dissociation constant K_d, described in Section 2.3. In many cases in cell biology, molecules must bind to one another but also be able to subsequently separate (dissociate). In other words, the binding needs to be reversible. Thus the binding cannot be too tight, or the molecules would not be able to dissociate when necessary. It is important to note that many large biological molecules are not hard, rigid structures, but rather can be somewhat malleable. Thus the binding of a molecule to another has the potential to induce a change in the shape of its binding partner. When the molecular complementarity increases after such interactions, the process is called *induced fit*.

As we discuss in Chapter 3, nearly all the chemical reactions that occur in cells depend on the binding properties of enzymes. These proteins not only speed up, or catalyze, reactions, but do so with a high degree of *specificity* because they are able to bind tightly to only one or a few related molecules. The specificity of intermolecular interactions and reactions, which depends on molecular complementarity, is essential for many processes critical to life.

KEY CONCEPTS OF SECTION 2.1

Covalent Bonds and Noncovalent Interactions

- The terms *hydrophilic, hydrophobic*, and *amphipathic/amphiphilic* refer to the tendency of molecules to be water-loving, incapable of interacting with water, and having features of or being tolerant of both, respectively. Hydrophilic molecules typically dissolve readily in water, whereas hydrophobic molecules are poorly soluble or insoluble in water.

- Covalent bonds consist of pairs of electrons shared by two atoms. Covalent bonds arrange the atoms of a molecule into a specific geometry.
- Many molecules in cells contain at least one asymmetric carbon atom, which is bonded to four dissimilar atoms. Such molecules can exist as stereoisomers (mirror images), designated D and L (see Figure 2-4), which have different biological activities. Nearly all amino acids are L isomers.
- Electrons may be shared equally or unequally in covalent bonds. Atoms that differ in electronegativity form polar covalent bonds, in which the bonding electrons are distributed unequally. One end of a polar bond has a partial positive charge and the other end has a partial negative charge (see Figure 2-5).
- Covalent bonds are stable in biological systems because the relatively high energies required to break them $(50-200\ \mathrm{kcal/mol})$ are much larger than the thermal kinetic energy available at room $(25\ ^{\circ}\mathrm{C})$ or body $(37\ ^{\circ}\mathrm{C}$ in mammals) temperatures.
- Noncovalent interactions between atoms are considerably weaker than covalent bonds, with energies ranging from about $1-5\ \mathrm{kcal/mol}$ (see Figure 2-6).
- Four main types of noncovalent interactions occur in biological systems: ionic bonds, hydrogen bonds, van der Waals interactions, and interactions due to the hydrophobic effect.
- Ionic bonds result from the electrostatic attraction between the positive and negative charges of ions. In aqueous solutions, all cations and anions are surrounded by a shell of bound water molecules (see Figure 2-7c). Increasing the salt (e.g., NaCl) concentration of a solution can weaken the relative strength of and even break the ionic bonds between biomolecules.
- In a hydrogen bond, a hydrogen atom covalently bonded to an electronegative atom associates with an acceptor atom whose nonbonding electrons attract the hydrogen (see Figure 2-8).
- Weak van der Waals interactions result from the attraction between transient dipoles associated with all molecules. They can form when two atoms approach each other closely (see Figure 2-10).
- In an aqueous environment, nonpolar molecules or nonpolar parts of larger molecules are driven together by the hydrophobic effect, thereby reducing the extent of their direct contact with water molecules (see Figure 2-11).
- Molecular complementarity is the lock-and-key fit between molecules whose shapes, charges, and other physical properties are complementary. Multiple noncovalent interactions can form between complementary molecules, causing them to bind tightly (see Figure 2-12), but cannot form between molecules that are not complementary.
- The high degree of binding specificity that results from molecular complementarity is one of the features that underlies intermolecular interactions in biology and thus is

essential for many processes critical to life.

2.2 Chemical Building Blocks of Cells

A common theme in biology is the construction of large **macromolecules** and macromolecular complexes (clusters of macromolecules) out of smaller molecular subunits, which can be thought of as building blocks. Often these subunits are similar or identical. The three main types of biological macromolecules — proteins, nucleic acids, and polysaccharides — are all **polymers** composed of multiple covalently linked small molecules, or **monomers** (Figure 2-13). **Proteins** are linear polymers containing up to several thousand amino acids linked by **peptide bonds**. **Nucleic acids** are linear polymers containing dozens to millions of nucleotides linked by **phosphodiester bonds**. **Polysaccharides** are linear or branched polymers of monosaccharides (sugars) such as glucose linked by **glycosidic bonds**.

FIGURE 2-13 Overview of the cell's principal chemical building blocks. *Top*: The three major types of biological macromolecules are each assembled by the polymerization of multiple small molecules (monomers) of a particular type: proteins from amino acids (see Chapter 3), nucleic acids from nucleotides (see Chapter 5), and polysaccharides from monosaccharides (sugars). Each monomer is covalently linked into the polymer by a reaction whose net result is loss of a water molecule (dehydration). *Bottom*: In contrast, phospholipid monomers noncovalently assemble into a bilayer structure, which forms the basis of all cellular membranes (see Chapter 10).

Although the actual mechanisms of covalent bond formation between monomers are complex, as we will see, the formation of a covalent bond between two monomers usually results in the net loss of a hydrogen (H) from one monomer and a hydroxyl (OH) from the other monomer — or the net loss of one water molecule — and can

therefore be thought of as a *dehydration reaction*. The cleavage of a covalent bond in a polymer is the result of the reverse reaction, or the addition of water, called *hydrolysis*. Hydrolysis can release a single monomer from the end of the polymer or can break the polymer into two shorter polymers, usually of unequal length, when the break occurs somewhere within the polymer chain. The covalent bonds that link monomers together are usually stable under normal biological conditions (e.g., 37 °C, neutral pH), so these biopolymers are stable and can perform a wide variety of jobs in cells, such as storing information, catalyzing chemical reactions, serving as structural elements that define cellular shape and movement, and many others. Macromolecular complexes can also be assembled using noncovalent interactions. The two-ply, or *bilayer*, structure of cellular membranes is built up by the noncovalent assembly of many thousands of small molecules called *phospholipids* (see Figure 2-13).

In this chapter, we focus on the chemical building blocks making up cells — amino acids, nucleotides, sugars, and phospholipids. The structure, function, and assembly of proteins, nucleic acids, polysaccharides, and biomembranes are discussed in subsequent chapters.

Amino Acids Differing Only in Their Side Chains Compose Proteins

The monomeric building blocks of proteins are 20 **amino acids**, which — when incorporated into a protein polymer — are sometimes called **residues**. All amino acids have a characteristic structure consisting of a central **alpha carbon atom** (C_α) bonded to four different chemical groups (Figure 2-14): an amino (—NH_2) group, a carboxyl or carboxylic acid (—COOH) group (hence the name *amino acid*), a hydrogen (H) atom, and one variable group, called a *side chain* or **R group**. The α carbon in all amino acids is asymmetric with the exception of glycine, whose R group is a hydrogen. Because they are asymmetric, these molecules can exist in two mirror-image forms, called by convention the *D* (dextro) and the *L* (levo) *isomers* (see Figure 2-4). The two isomers cannot be interconverted (one made identical to the other)

without breaking and then re-forming a chemical bond in one of them. With rare exceptions, only the L forms of amino acids are found in proteins. However, D amino acids are prevalent in bacterial cell walls and other microbial products.

FIGURE 2-14 The 20 common amino acids used to build proteins. The side chain (R group; red) determines the distinctive properties of each amino acid and is the basis for grouping amino acids into three main categories: hydrophobic, hydrophilic, and special. Shown are the ionized forms that exist at the pH (~ 7) of the cytosol. In parentheses are the three-letter and one-letter abbreviations for each amino acid.

To understand the three-dimensional structures and functions of proteins, discussed in detail in Chapter 3, you must be familiar with some of the distinctive properties of

amino acids. These properties are determined in part by their side chains. You need not memorize the detailed structure of each type of side chain to understand how proteins work because amino acids can be classified into several broad categories based on the size, shape, charge, hydrophobicity (a measure of water solubility), and chemical reactivity of their side chains (Figure 2-14).

Amino acids with nonpolar side chains, called *hydrophobic amino acids*, are poorly soluble in water. The larger the nonpolar side chain, the more hydrophobic the amino acid. The side chains of *alanine, valine, leucine*, and *isoleucine* are linear or branched hydrocarbons that do not form a ring, and they are therefore called *aliphatic amino acids*. These amino acids are all nonpolar, as is *methionine*, which is similar to them except that it contains one sulfur atom. *Phenylalanine, tyrosine*, and *tryptophan* have large, hydrophobic, aromatic rings in their side chains. In later chapters, we will see in detail how hydrophobic side chains under the influence of the hydrophobic effect often pack into the interior of proteins or line the surfaces of proteins that are embedded within hydrophobic regions of biomembranes.

Amino acids with polar side chains are called *hydrophilic amino acids*. The most hydrophilic of these amino acids is the subset with side chains that are charged (ionized) at the pH typical of biological fluids ($\sim$7) both inside and outside the cell (see Section 2.3). *Arginine* and *lysine* have positively charged side chains and are called *basic amino acids; aspartic acid* and *glutamic acid* have negatively charged side chains due to the carboxylic acid groups in their side chains (their charged forms are called *aspartate* and *glutamate*) and are called *acidic amino acids*. A fifth amino acid, *histidine*, has a side chain containing a ring with two nitrogens, called *imidazole*. The imidazole ring can shift from being positively charged to uncharged in response to small changes in the acidity of its environment (defined as pH, see Section 2.3):

The activities of many proteins are modulated by shifts in environmental acidity (pH) through protonation or deprotonation of histidine side chains. *Asparagine* and *glutamine* are uncharged amino acids but have polar side chains containing amide groups with extensive hydrogen-bonding capacities. Similarly, *serine* and *threonine* are uncharged but have polar hydroxyl groups, which also participate in hydrogen bonds with other polar molecules.

Finally, *cysteine, glycine,* and *proline* play special roles in proteins because of the unique properties of their side chains. The side chain of cysteine contains a reactive *sulfhydryl group* (—*SH*). On release of a proton (H^+), a sulfhydryl group is converted into a thiolate anion (S^-). Thiolate anions in certain enzymes can play important roles in catalysis, notably in some proteases that destroy proteins. In many proteins, especially those secreted from cells or that extend outward from the plasma membrane into the extracellular fluid, each of two adjacent sulfhydryl groups can be oxidized, each releasing a proton and an electron, to form a covalent *disulfide bond* (—*S*—*S*—):

Disulfide bonds serve to cross-link regions within a single polypeptide chain (intramolecular cross-linking) or between two separate chains (intermolecular cross-linking). Disulfide bonds stabilize the folded structure of some proteins.

The smallest amino acid, *glycine*, has a single hydrogen atom as its R group. Its small size allows it to fit into tight spaces. We will see an example of this tight fit when we examine the structure of the most abundant protein in humans, *collagen* (see Chapter 20).

Unlike the side chains of the other common amino acids, the side chain of proline (pronounced *pro-leen*) bends around to form a ring by covalently bonding to the nitrogen atom in the amino group attached to the C_α. As a result, proline is very rigid, and its amino group is not available for typical hydrogen bonding. The presence of

proline in a protein creates a fixed kink in the polymer chain, limiting how it can fold in the vicinity of the proline residue.

Some amino acids are more abundant in proteins than others. Cysteine, tryptophan, and methionine are not common amino acids: together, they constitute approximately 5 percent of the amino acids in a typical protein. Four amino acids — leucine (hydrophobic), serine (polar), lysine (positively charged), and glutamic acid (negatively charged) — are the most abundant amino acids, constituting 32 percent of all the residues in a typical protein. However, the amino acid compositions of particular proteins may vary widely from these values.

Humans and other mammals can synthesize 11 of the 20 amino acids. The other nine are called *essential amino acids* and must be included in the diet to permit normal protein production. These essential amino acids are phenylalanine, valine, threonine, tryptophan, isoleucine, methionine, leucine, lysine, and histidine. Adequate provision of these essential amino acids in feed is key to the livestock industry. Indeed, a genetically engineered variety of corn with a high lysine content is now in use as an enhanced feed to promote the growth of animals. ■

Although cells use the 20 amino acids shown in Figure 2-14 in the *initial* synthesis of proteins, analysis of cellular proteins reveals that they contain over 100 different amino acids. The difference is due to the covalent modification by the addition of a variety of chemical groups to some amino acids after they are incorporated into proteins (Figure 2-15). One important modification is the addition of acetyl groups (CH_3CO) to amino acids, a process known as acetylation. Acetylation of the amino group of the N-terminal residue is the most common form of amino acid covalent modification, affecting an estimated 80 percent of all proteins:

Acetylated N-terminus

This modification may play an important role in controlling the life span of proteins within cells because many non-acetylated proteins are rapidly degraded.

FIGURE 2-15 Common modifications of amino acid side chains in proteins. These modified residues and numerous others are formed by addition of various chemical groups (red) to the amino acid side chains during or after synthesis of a polypeptide chain.

Another important modification is the addition of a phosphate group (PO_4) to hydroxyl groups in serine, threonine, and tyrosine residues, a process known as

phosphorylation. We will encounter numerous examples of proteins whose activity is regulated by reversible phosphorylation and dephosphorylation. A well-known site of phosphorylation in bacteria, fungi, and plants is the nitrogen in the side chain of histidine, but the prevalence and functional significance of this modification in higher eukaryotes, such as mammals, has not been well-defined. Like phosphorylation and dephosphorylation, controlled methylation and demethylation of arginine and lysine side chains on proteins are important regulatory processes. For example, methylation of these side chains on proteins called *histones* is an important regulator of gene expression in eukaryotes (see Chapter 8). The side chains of asparagine, serine, and threonine are sites for glycosylation, the attachment of linear and branched carbohydrate chains. Many secreted proteins and membrane proteins contain glycosylated residues, and the reversible modification of hydroxyl groups on specific serines and threonines by a sugar called *N-acetylglucosamine* also appears to regulate protein activities inside cells. Other amino acid modifications found in selected proteins include the hydroxylation of proline and lysine residues in collagen (see Chapter 20), the methylation of histidine residues in membrane receptors, and the γ-carboxylation of glutamate in blood-clotting factors such as prothrombin. Deamidation of asparagine and glutamine to form the corresponding acidic amino acids, aspartate and glutamate, also occurs.

Five Different Nucleotides Are Used to Build Nucleic Acids

Two types of chemically similar nucleic acids, **DNA (deoxyribonucleic acid)** and **RNA (ribonucleic acid)**, are the cell's principal molecules that carry genetic information. RNAs can also help catalyze chemical reactions. DNA and RNA polymers are built from monomers called **nucleotides**. All nucleotides have a common three-part structure: a phosphate group is linked by a phosphoester bond to a pentose (five-carbon) sugar, and the pentose sugar in turn is linked to a nitrogen- and carbon-containing ring structure commonly referred to as a *base* (Figure 2-16a). In RNA, the pentose is *r*ibose; in DNA, it is *d*eoxyribose, which has a proton, rather than a hydroxyl group, at position 2′ (Figure 2-16b). (We describe the structures of sugars in

more detail below) The bases *adenine, guanine*, and *cytosine* (Figure 2-17) are found in both DNA and RNA; *thymine* is found only in DNA, and *uracil* is found only in RNA. The bases are often abbreviated *A, G, C, T*, and *U*, respectively; these same single-letter abbreviations are also commonly used to denote all the nucleotides in nucleic acid polymers.

FIGURE 2-16 Common structure of nucleotides. (a) Adenosine 5′-monophosphate (AMP), a nucleotide present in RNA. By convention, the carbon atoms of the pentose sugar in nucleotides are numbered with primes. In natural nucleotides, the 1′ carbon is joined by a β linkage to the base (in this case, adenine); both the base (blue) and the phosphate on the 5′ hydroxyl (red) extend above the plane of the sugar ring. (b) Ribose and deoxyribose, the pentoses in RNA and DNA, respectively.

FIGURE 2-17 Chemical structures of the principal bases in nucleic acids. In nucleic acids and nucleotides, nitrogen 9 of purines and nitrogen 1 of pyrimidines (red) are bonded to the 1′ carbon of ribose or deoxyribose. U is found only in RNA, and T is found only in DNA. Both RNA and DNA contain A, G, and C.

Adenine and guanine are **purines**, bases that contain a pair of fused rings; cytosine, thymine, and uracil are **pyrimidines**, bases that contain a single ring (see Figure 2-17). In nucleotides, the 1′ carbon atom of the sugar (ribose or deoxyribose) is attached to the nitrogen atom at position 9 of a purine (N_9) or at position 1 of a pyrimidine (N_1). For example, the connection of deoxyribose to a purine base in the nucleotide adenosine 5′-monophosphate (AMP) is shown in Figure 2-16a. Due to the phosphate group, nucleotides are acidic: under normal intracellular conditions the phosphate

group releases hydrogen ions (H^+), becoming negatively charged (see Figure 2-16a). Most nucleic acids in cells are associated with proteins, which form both ionic interactions with the negatively charged phosphates and other noncovalent interactions with other portions of the nucleic acid.

Cells and extracellular fluids in organisms contain small concentrations of **nucleosides**, combinations of a base and a sugar without a phosphate group. Nucleotides are nucleosides that have one, two, or three phosphate groups covalently attached to the ribose via an ester bond. An ester bond is a covalent bond linking an acid, such as a carboxylic acid or a phosphoric acid, with an alcohol. The formation of such a bond, called *esterification*, is accompanied by the release of a hydroxyl (—OH) group from the acid and a proton (—H) from the hydroxyl group on the alcohol, which together form a water molecule. In a nucleotide, a phosphoric acid is esterified with the 5′ hydroxyl group of the ribose (see Figure 2-16a). Nucleoside monophosphates have a single esterified phosphate (see Figure 2-16a); nucleoside diphosphates contain a pyrophosphate group:

Pyrophosphate

Nucleoside triphosphates have a third phosphate. Table 2-3 lists the names of the nucleosides and nucleotides in nucleic acids and the various forms of nucleoside phosphates. Later in this chapter (Section 2.4), we will consider in detail the structure of the nucleoside triphosphate ATP (see Figures 2-1d and 2-31). The nucleoside triphosphates are used in the synthesis of nucleic acids, as we explain in Chapter 5. Among their other functions in the cell, GTP participates in intracellular signaling and acts as an energy reservoir, particularly in protein synthesis, and ATP is the most widely used biological energy carrier.

TABLE 2-3 • Terminology of Nucleosides and Nucleotides

Bases		Purines		Pyrimidines	
		Adenine (A)	**Guanine (G)**	**Cytosine (C)**	**Uracil (U)** **Thymine (T)**
Nucleosides	in RNA	Adenosine	Guanosine	Cytidine	Uridine
	in DNA	Deoxyadenosine	Deoxyguanosine	Deoxycytidine	Deoxythymidine
Nucleotides	in RNA	Adenylate	Guanylate	Cytidylate	Uridylate
	in DNA	Deoxyadenylate	Deoxyguanylate	Deoxycytidylate	Deoxythymidylate
Nucleoside monophosphates		AMP	GMP	CMP	UMP
Nucleoside diphosphates		ADP	GDP	CDP	UDP
Nucleoside triphosphates		ATP	GTP	CTP	UTP
Deoxynucleoside mono-, di-, and triphosphates		dAMP, etc.	dGMP, etc.	dCMP, etc.	dTMP, etc.

Monosaccharides Covalently Assemble into Linear and Branched Polysaccharides

The building blocks of the polysaccharides are the simple sugars, or **monosaccharides**. Monosaccharides are **carbohydrates**, which are literally covalently bonded combinations of carbon atoms ("carbo") and water molecules ("hydrate") in a one-to-one ratio $(CH_2O)_n$, where n equals 3, 4, 5, 6, or 7. **Hexoses** ($n = 6$) and **pentoses** ($n = 5$) are the most common monosaccharides. All monosaccharides contain hydroxyl (—OH) groups and either an aldehyde or a keto group:

Many biologically important sugars are hexoses, including glucose, mannose, and galactose (Figure 2-18). Mannose is identical to glucose except that the orientation of the groups bonded to carbon 2 is reversed — they are stereoisomers (also called *epimers*). Similarly, galactose, another hexose, differs from glucose only in the orientation of the groups attached to carbon 4. Interconversion of glucose and mannose or galactose requires the breaking and making of covalent bonds; such reactions are carried out by enzymes called *epimerases*.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 2-18 Chemical structures of hexoses. All hexoses have the same chemical formula ($C_6H_{12}O_6$) and contain an aldehyde or a keto group. (a) The ring forms of D-glucose are generated from the linear molecule by reaction of the aldehyde at carbon 1 with the hydroxyl on carbon 5 or carbon 4. The three forms are readily interconvertible, although the pyranose form (*right*) predominates in biological systems. (b) In D-mannose and D-galactose, the configuration of the H (green) and OH (blue) bound to one carbon atom differs from that in glucose. These sugars, like glucose, exist primarily as pyranoses (six-member rings).

D-Glucose ($C_6H_{12}O_6$) is one of the principal external sources of energy for most cells in complex multicellular organisms. It can exist in three different forms: a linear structure and two different hemiacetal ring structures (Figure 2-18a). If the aldehyde group on carbon 1 combines with the hydroxyl group on carbon 5, the result is the formation of D-glucopyranose, a hemiacetal containing a six-atom (usually called a

six-membered) ring. In the α anomer of D-glucopyranose, the hydroxyl group attached to carbon 1 points *downward* from the ring, as shown in Figure 2-18a; in the β anomer, this hydroxyl points *upward*. In aqueous solution, the α and β anomers readily interconvert spontaneously; at equilibrium there is about one-third α anomer and two-thirds β, with very little of the open-chain form. Because enzymes can distinguish between the α and β anomers of D-glucose, these forms have distinct biological roles. Condensation of the hydroxyl group on carbon 4 of the linear glucose with its aldehyde group results in the formation of D-glucofuranose, a hemiacetal containing a five-membered ring. Although all three forms of D-glucose exist in biological systems, the pyranose (six-membered ring) form is by far the most abundant.

The pyranose ring in Figure 2-18a is depicted as planar. In fact, because of the tetrahedral geometry of each of the five carbon atoms, the most stable conformation of a pyranose ring has a nonplanar, chairlike shape. In this conformation, each bond from a ring carbon to a nonring atom (e.g., H or O) is either nearly perpendicular to the ring — referred to as *axial (a)* — or nearly in the plane of the ring — referred to as *equatorial (e)*:

Disaccharides, formed from two monosaccharides, are the simplest polysaccharides. The disaccharide lactose, composed of galactose and glucose, is the major sugar in milk; the disaccharide sucrose, composed of glucose and fructose, is a principal product of plant photosynthesis and is refined into common table sugar (Figure 2-19).

FIGURE 2-19 Formation of the disaccharides lactose and sucrose. In any glycosidic linkage, the anomeric carbon of one sugar molecule (in either the α or β conformation) is linked to a hydroxyl oxygen on another sugar molecule. The linkages are named accordingly; thus lactose contains a $\beta(1 \rightarrow 4)$ bond, and sucrose contains an $\alpha(1 \rightarrow 2)$ bond.

Larger polysaccharides contain dozens to hundreds of monosaccharide units. They can function as reservoirs for glucose, as structural components, or as adhesives that help hold cells together in tissues. The most common storage carbohydrate in animal cells is **glycogen**, a very long, highly branched polymer of glucose. As much as 10 percent of the liver by weight can be glycogen. The primary storage carbohydrate in plant cells, **starch**, is also a glucose polymer. It occurs in an unbranched form (amylose) and a lightly branched form (amylopectin). Both glycogen and starch are composed of the α anomer of glucose. In contrast, **cellulose**, the major constituent of plant cell walls, is an unbranched polymer of the β anomer of glucose. Cellulose confers stiffness to many plant structures (see Chapter 20). Human digestive enzymes can hydrolyze the α glycosidic bonds in starch but not the β glycosidic bonds in cellulose. Many species of plants, bacteria, and molds produce cellulose-degrading enzymes. Cows and termites can break down cellulose because they harbor cellulose-degrading bacteria in their gut. Bacterial cell walls consist of **peptidoglycan** rather than cellulose. A peptidoglycan has a polysaccharide chain cross-linked by peptide cross-bridges, which confer rigidity and cell shape. Human tears and gastrointestinal fluids contain lysozyme, an enzyme capable of hydrolyzing peptidoglycan in the bacterial cell wall.

The enzymes that make the glycosidic bonds, linking monosaccharides into polysaccharides, are specific for the α or β anomer of one sugar and a particular hydroxyl group on the other. In principle, any two sugar molecules can be linked in a variety of ways because each monosaccharide has multiple hydroxyl groups that can participate in the formation of glycosidic bonds. Furthermore, any one monosaccharide has the potential to be linked to more than one other monosaccharide, thus generating a branch point and nonlinear polymers. Glycosidic bonds are usually formed between the growing polysaccharide chain and a covalently modified form of a monosaccharide. Such modifications include the addition of a phosphate (e.g., glucose 6-phosphate) or a nucleotide (e.g., UDP-galactose):

Glucose 6-phosphate **UDP-galactose**

The epimerase enzymes that interconvert different monosaccharides often do so using the nucleotide sugars rather than the unmodified, or *free*, sugars.

Many complex polysaccharides contain modified sugars that are covalently linked to various small groups, particularly amino, sulfate, and acetyl groups. Such modifications are abundant in **glycosaminoglycans**, major polysaccharide components of the extracellular matrix that we describe in Chapter 20.

As you can see here and in many examples throughout this book, a relatively simple set of monosaccharides can be assembled into a wide variety of polysaccharides with dramatically different biological functions.

Phospholipids Associate Noncovalently to Form the Basic Bilayer Structure of Biomembranes

Biomembranes are large, flexible sheets with a two-ply, or bilayer, structure. They serve as the boundaries of cells and their intracellular organelles and form the outer surfaces of some viruses. Membranes literally define what is a cell (the outer membrane and the contents within the membrane) and what is not (the extracellular space outside the membrane). Unlike proteins, nucleic acids, and polysaccharides, membranes are assembled by the *noncovalent* association of their component building blocks. The primary building blocks of all biomembranes are **phospholipids**, whose physical properties are responsible for the formation of the sheet-like bilayer structure of membranes. In addition to phospholipids, biomembranes can contain a variety of other molecules, including cholesterol, glycolipids, and proteins. The structure and function of biomembranes will be described in detail in Chapter 10. Here we will focus on the phospholipids in biomembranes.

To understand the structure of a phospholipid molecule, we have to understand each of its component parts and how they are assembled. As we will see shortly, a phospholipid molecule consists of two long-chain, nonpolar fatty acid groups linked (usually by an ester bond) to small, highly polar groups. These polar groups typically include a short organic molecule such as glycerol (trihydroxy propane), a phosphate, and typically a small organic molecule (Figure 2-20).

FIGURE 2-20 Phosphatidylcholine, a typical phosphoglyceride. All phosphoglycerides are amphipathic phospholipids, having a hydrophobic tail (yellow) and a hydrophilic head (blue) in which glycerol is linked via a

phosphate group to an alcohol. Either or both of the fatty acyl side chains in a phosphoglyceride may be saturated or unsaturated. In phosphatidic acid (red), the simplest phospholipid, the phosphate is not linked to an alcohol.

Fatty acids consist of a hydrocarbon chain attached to a carboxyl group (—COOH). Like glucose, fatty acids are an important energy source for many cells (see Chapter 12). They differ in length, although the predominant fatty acids in cells have an even number of carbon atoms, usually 14, 16, 18, or 20. The major fatty acids in phospholipids are listed in Table 2-4. Fatty acids are often designated by the abbreviation *Cx:y*, where *x* is the number of carbons in the chain and *y* is the number of double bonds. Fatty acids containing 12 or more carbon atoms are nearly insoluble in aqueous solutions because of their long hydrophobic hydrocarbon chains.

TABLE 2-4 • Fatty Acids That Predominate in Phospholipids

Common Name of Acid (ionized form in parentheses)	Abbreviation	Chemical Formula
Saturated Fatty Acids		
Myristic (myristate)	C14:0	$CH_3(CH_2)_{12}COOH$
Palmitic (palmitate)	C16:0	$CH_3(CH_2)_{14}COOH$
Stearic (stearate)	C18:0	$CH_3(CH_2)_{16}COOH$
Unsaturated Fatty Acids		
Oleic (oleate)	C18:1	$CH_3(CH_2)_7CH{=}CH(CH_2)_7COOH$
Linoleic (linoleate)	C18:2	$CH_3(CH_2)_4CH{=}CHCH_2CH{=}CH(CH_2)_7COOH$
Arachidonic (arachidonate)	C20:4	$CH_3(CH_2)_4(CH{=}CHCH_2)_3CH{=}CH(CH_2)_3COOH$

Fatty acids in which all the carbon-carbon bonds are single bonds — that is, the fatty acids have no carbon-carbon double bonds — are said to be **saturated**; those with at least one carbon-carbon double bond are called **unsaturated**. Unsaturated fatty acids with more than one carbon-carbon double bond are referred to as **polyunsaturated**. Two *essential* polyunsaturated fatty acids, linoleic acid (C18:2) and linolenic acid

(C18:3), cannot be synthesized by mammals and must be supplied in their diet. Mammals can synthesize other common fatty acids.

In phospholipids, fatty acids are covalently attached to another molecule by esterification. In the combined molecule formed by this reaction, the part derived from the fatty acid is called an *acyl group*, or *fatty acyl group*. The most common phospholipids are the **phosphoglycerides**, which contain two acyl groups attached to two of the three hydroxyl groups of glycerol (see Figure 2-20). Other types of phospholipids are described in Chapter 10 (also see Figure 10-8).

In phosphoglycerides, one hydroxyl group of the glycerol is esterified to phosphate while the other two are normally esterified to fatty acids. The simplest phospholipid, phosphatidic acid, contains only these components. Phospholipids such as phosphatidic acids are not only membrane building blocks but also important signaling molecules. Lysophosphatidic acid, for example, can be a potent inducer of cell division (called a **mitogen**). In this phospholipid, the acyl chain at the 2 position (attached to the hydroxyl group on the central carbon of the glycerol) has been removed, so the molecule is relatively water soluble. In most phospholipids found in membranes, the phosphate group is also esterified to a hydroxyl group on another hydrophilic compound. In phosphatidylcholine, for example, the phosphate is covalently attached to the small molecule called *choline* (see Figure 2-20).

The negatively charged phosphate, as well as the charged or polar groups esterified to it, can interact strongly with water. The phosphate and its associated esterified group constitute the *head* group of a phospholipid, which is hydrophilic, whereas the fatty acyl chains, the *tails*, are hydrophobic. Other common phosphoglycerides and associated head groups are shown in Table 2-5. Molecules such as phospholipids that have both hydrophobic and hydrophilic regions are called *amphipathic*. In Chapter 10, we will see how the amphipathic properties of phospholipids allow their assembly into sheet-like bilayers in which the fatty acyl tails point into the center of the sheet and the head groups point outward toward the aqueous environment (see Figure 2-13 bottom).

TABLE 2-5 • Common Phosphoglycerides and Head Groups

Common Phosphoglycerides	Head Group
Phosphatidylcholine	 Choline
Phosphatidylethanolamine	 Ethanolamine
Phosphatidylserine	 Serine
Phosphatidylinositol	 Inositol

Fatty acyl groups also can be covalently linked in other fatty molecules, including **triacylglycerols** (or **triglycerides**), which contain three acyl groups esterified to glycerol:

Triacylglycerol

They can also be covalently attached to the very hydrophobic molecule cholesterol, an alcohol, to form cholesteryl esters:

Cholesterol

Cholesteryl ester

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

Triglycerides and cholesteryl esters are extremely water-insoluble molecules in which fatty acids and cholesterol are either stored or transported. Triglycerides are the storage form of fatty acids in the fat cells of adipose tissue and are the principal components of dietary fats. Cholesteryl esters and triglycerides are transported between tissues through the bloodstream in specialized carriers called *lipoproteins* (see Chapter 14).

We saw previously that the fatty acids, which are key components of both phospholipids and triglycerides, can be either saturated or unsaturated. An important consequence of the carbon-carbon double bond (C=C) in an unsaturated fatty acid is that two stereoisomeric configurations, cis and trans, are possible around each of these bonds:

A cis double bond introduces a rigid kink in the otherwise flexible straight acyl chain of a saturated fatty acid (Figure 2-21). In general, the unsaturated fatty acids in biological systems contain only cis double bonds. Saturated fatty acids without the kink can pack together tightly and so have higher melting points than unsaturated fatty acids. The main fatty molecules in butter are triglycerides with saturated fatty acyl chains, which is why butter is usually solid at room temperature. Unsaturated fatty acids or fatty acyl chains with the cis double bond kink cannot pack as closely together as saturated fatty acyl chains. Thus vegetable oils, composed of triglycerides with unsaturated fatty acyl groups, usually are liquid at room temperature. Vegetable and similar oils may be partially hydrogenated to convert some of their unsaturated fatty acyl chains to saturated fatty acyl chains. As a consequence, the hydrogenated vegetable oil can be molded into solid sticks of margarine. A by-product of the hydrogenation reaction is the conversion of some of the fatty acyl chains into trans fatty acids, popularly called *trans fats*. These trans fats, found in partially hydrogenated margarine and other food products, are not natural. Saturated and trans fatty acids have similar physical properties; for example, they tend to be solids at room temperature. Their consumption, relative to the consumption of unsaturated fats, is associated with increased plasma cholesterol levels and is discouraged by some nutritionists. ■

FIGURE 2-21 The effect of a double bond on the shape of fatty acids. Shown are chemical structures of the ionized form of palmitic acid, a saturated fatty acid with 16 C atoms, and oleic acid, an unsaturated one with 18 C atoms. In saturated fatty acids, the hydrocarbon chain is often linear; the cis double bond in oleate creates a rigid kink in the hydrocarbon chain.

KEY CONCEPTS OF SECTION 2.2

Chemical Building Blocks of Cells

- Macromolecules are polymers of monomer subunits linked together by covalent bonds via dehydration reactions. Three major types of macromolecules are found in cells: proteins, composed of amino acids linked by peptide bonds; nucleic acids, composed of nucleotides linked by phosphodiester bonds; and polysaccharides, composed of monosaccharides (sugars) linked by glycosidic bonds (see Figure 2-13). Phospholipids, the fourth major chemical building block, assemble noncovalently into biomembranes.
- Differences in the size, shape, charge, hydrophobicity, and reactivity of the side chains of the 20 common amino acids determine the chemical and structural properties of proteins (see Figure 2-14). The three general categories into which the side chains fall are hydrophobic, hydrophilic (basic, acidic, polar), and special (see Figure 2-14). It is helpful to remember which amino acids fall into each of these categories.
- The bases in the nucleotides composing DNA and RNA are carbon- and nitrogen-containing rings attached to a pentose sugar. They form two groups: the purines, with two rings — adenine (A) and guanine (G) — and the pyrimidines, with one ring — cytosine (C), thymine (T), and uracil (U) (see Figure 2-17). A, G, T, and C are found in DNA, and A, G, U, and C are found in RNA.
- Glucose and other hexoses can exist in three forms: an open-chain linear structure, a six-member (pyranose) ring, and a five-member (furanose) ring (see Figure 2-18). In biological systems, the pyranose form of D-glucose predominates.
- Glycosidic bonds are formed between either the α or the β anomer of one sugar and a hydroxyl group on another sugar, leading to formation of disaccharides and other polysaccharides (see Figure 2-19).
- Phospholipids are amphipathic molecules with a hydrophobic tail (often two fatty acyl chains) connected by a small organic molecule (often glycerol) to a hydrophilic head (see Figure 2-20).
- The long hydrocarbon chain of a fatty acid may be saturated (containing no carbon-carbon double bonds) or unsaturated (containing one or more double bonds). Fatty substances such as butter that have primarily saturated fatty acyl chains tend to be solid at room temperature, whereas unsaturated fats with cis double bonds have kinked chains that cannot pack closely together and so tend to be liquids at room temperature.

2.3 Chemical Reactions and Chemical Equilibrium

We now shift our discussion to chemical reactions in which bonds, primarily covalent bonds in *reactant* chemicals, are broken and new bonds are formed to generate reaction *products*. At any one time, several hundred different kinds of chemical reactions are occurring simultaneously in every cell, and many chemicals can, in principle, undergo multiple chemical reactions. Both the *extent* to which reactions can proceed and the *rate* at which they take place determine the chemical composition of cells. In this section, we discuss the concepts of equilibrium and steady state as well as dissociation constants and pH. These concepts will arise again and again throughout this textbook, so it is important for you to be familiar with them. In Section 2.4, we discuss how energy influences the extents and rates of chemical reactions.

A Chemical Reaction Is in Equilibrium When the Rates of the Forward and Reverse Reactions Are Equal

When reactants first mix together — before any products have been formed — the rate of the forward reaction to form products is determined in part by the reactants' initial concentrations, which

determine the likelihood of reactants bumping into one another and reacting (Figure 2-22). As the reaction products accumulate, the concentration of each reactant decreases, and so does the forward reaction rate. Meanwhile, some of the product molecules begin to participate in the reverse reaction, which re-forms the reactants. The ability of a reaction to go backward is called *microscopic reversibility*. The reverse reaction is slow at first but speeds up as the concentration of product increases. Eventually, the rates of the forward and reverse reactions become equal, so that the concentrations of reactants and products stop changing. The system is then said to be in **chemical equilibrium** (plural, *equilibria*).

FIGURE 2-22 Time dependence of the rates of a chemical reaction. The forward and reverse rates of a reaction depend in part on the initial

concentrations of reactants and products. The net forward reaction rate slows as the concentration of reactants decreases, whereas the net reverse reaction rate increases as the concentration of products increases. At equilibrium, the rates of the forward and reverse reactions are equal, and the concentrations of reactants and products remain constant.

The ratio of the concentrations of the products to the concentrations of the reactants when they reach equilibrium, called the **equilibrium constant (K_{eq}),** is a fixed value. Thus K_{eq} provides a measure of the extent to which a reaction occurs by the time it reaches equilibrium. The rate of a chemical reaction can be increased by a **catalyst**, a chemical that accelerates the making and breaking of covalent bonds in other molecules but itself is not permanently changed during a reaction. Although a catalyst increases the reaction rate, it does not change the equilibrium constant (see Section 2.4).

The Equilibrium Constant Reflects the Extent of a Chemical Reaction

For any chemical reaction, K_{eq} depends on the chemical nature of the reactants and products, the temperature, and the pressure (particularly in reactions involving gases). Under standard physical conditions (25 $^{\circ}$C and 1 atm pressure for biological systems), K_{eq} is always the same for a given reaction, whether or not a catalyst is present.

Consider the general reaction with three reactants and three products,

$$\mathrm{aA} + \mathrm{bB} + \mathrm{cC} \rightleftharpoons \mathrm{zZ} + \mathrm{yY} + \mathrm{xX} \tag{2-1}$$

where capital letters represent particular molecules or atoms and lowercase letters represent the number of each in the reaction. For this reaction, the formula for the equilibrium constant is given by

$$K_{\mathrm{eq}} = \frac{[\mathrm{X}]^{\mathrm{x}}[\mathrm{Y}]^{\mathrm{y}}[\mathrm{Z}]^{\mathrm{z}}}{[\mathrm{A}]^{\mathrm{a}}[\mathrm{B}]^{\mathrm{b}}[\mathrm{C}]^{\mathrm{c}}} \tag{2-2}$$

where brackets denote the concentrations of the molecules. In Equation 2-2, the concentrations of reactants and products are those present at equilibrium. The rate of the forward reaction (left to right in Equation 2-1) is

$$\mathrm{Rate}_{\mathrm{forward}} = k_{\mathrm{f}}[\mathrm{A}]^{\mathrm{a}}[\mathrm{B}]^{\mathrm{b}}[\mathrm{C}]^{\mathrm{c}}$$

where k_{f} is the **rate constant** for the forward reaction. Similarly, the rate of the reverse reaction (right to left in Equation 2-1) is

$$\mathrm{Rate}_{\mathrm{reverse}} = k_{\mathrm{r}}[\mathrm{X}]^{\mathrm{x}}[\mathrm{Y}]^{\mathrm{y}}[\mathrm{Z}]^{\mathrm{z}}$$

where k_r is the rate constant for the reverse reaction. These reaction rate equations apply whether or not the reaction has reached equilibrium. It is important to remember that the forward and reverse rates of a reaction can change because of changes in reactant or product concentrations, yet at the same time the forward and reverse rate constants do not change; hence the name *constant*. Confusing rates and rate constants is a common error. At equilibrium the forward and reverse rates are equal, so $\text{Rate}_{\text{forward}}/\text{Rate}_{\text{reverse}} = 1$. By rearranging these equations, we can express the equilibrium constant as the ratio of the rate constants:

$$K_{\text{eq}} = \frac{k_{\text{f}}}{k_{\text{r}}} \tag{2-3}$$

The concept of K_{eq} is particularly helpful when we want to think about the energy that is released or absorbed when a chemical reaction occurs. We will discuss this concept in considerable detail in Section 2.4.

Chemical Reactions in Cells Are at Steady State

Under appropriate conditions and given sufficient time, a single biochemical reaction carried out in a test tube eventually reaches

equilibrium, at which the concentrations of reactants and products do not change with time because the rates of the forward and reverse reactions are equal. Within cells, however, many reactions are linked in pathways in which the fate of the product of one reaction is not simply to remain unchanged or to be reconverted via a reverse reaction to the reactants. For example, the product of one reaction might serve as a reactant in another reaction, or it might be pumped out of the cell. In this more complex situation, the original reaction can never reach equilibrium because some of the product molecules do not have a chance to be converted back to reactants. Nevertheless, in such non-equilibrium conditions, the rate of formation of a substance can be equal to the rate of its consumption, and as a consequence, the concentration of that substance remains constant over time. In such circumstances, the system of linked reactions for producing and consuming that substance is said to be in a **steady state** (Figure 2-23). One consequence of such linked reactions is that they prevent the accumulation of excess intermediates, protecting cells from the harmful effects of intermediates that are toxic at high concentrations. When the concentration of a product of an ongoing reaction is not changing over time, it might be a consequence of a state of equilibrium, or it might be a consequence of a steady state. In biological systems, when metabolite concentrations, such as blood glucose levels, are not changing with time — a condition called *homeostasis* (from the Greek *homoios* meaning “similar” and

stasis meaning “standing still or stability”) — it is a consequence of a steady state rather than equilibrium.

FIGURE 2-23 Comparison of reactions at equilibrium and at steady state. (a) In the test tube, a biochemical reaction ($A \rightarrow B$) eventually reaches equilibrium, at which the rates of the forward and reverse reactions are equal (as indicated by the reaction arrows of equal length), and the relative concentrations of the reactants (A) and products (B) do not change (in this example, the B:A ratio at equilibrium is 9:3). (b) In metabolic pathways within cells, the product B is commonly consumed — in this example, by conversion to C. A pathway of linked reactions is at steady state when the rate of formation of the intermediates (e.g., B) equals its rate of consumption. As indicated by the unequal length of the arrows, the individual reversible reactions constituting a metabolic pathway do not reach equilibrium. Moreover, the concentrations of the intermediates at steady state can differ from what they would be at equilibrium.

Dissociation Constants of Binding Reactions Reflect the Affinity of Interacting Molecules

The concept of equilibrium also applies to the binding of one molecule to another even when there are no covalent changes to either molecule. Many important cellular processes depend on such binding reactions, which involve the making and breaking of various noncovalent interactions rather than covalent bonds, as discussed above. In some cases, the noncovalent binding can be relatively weak, or loose; in other cases the binding can be very strong, or tight. A common example is the binding of a **ligand** (e.g., the hormone insulin or adrenaline) to its **receptor** on the surface of a cell, which triggers an intracellular signaling pathway (see Chapter 15). Another example is the binding of a protein to a specific sequence of bases in a molecule of DNA, which frequently causes the expression of a nearby gene to increase or decrease (see Chapter 8). Here we will review the most common approach used to think about how tightly or loosely two molecules bind to one another.

To illustrate the general approach, let's calculate the extent to which a protein (P) binds to a particular, short sequence of As, Ts, Gs, and Cs present in a relatively long DNA molecule (D) at equilibrium, forming a protein-DNA complex (PD):

$$\mathrm{P} + \mathrm{D} \rightleftharpoons \mathrm{PD}$$

Most commonly, binding reactions are described in terms of the **dissociation constant** ($K_\mathbf{d}$), which is the reciprocal of the equilibrium constant ($K_\mathrm{d} = 1/K_\mathrm{eq}$). For this binding reaction, the dissociation constant is calculated from the concentrations of the three components when they are at equilibrium by

$$K_\mathrm{d} = \frac{[\mathrm{P}][\mathrm{D}]}{[\mathrm{PD}]} \tag{2-4}$$

It is worth noting that in such a binding reaction, when half of the DNA is bound to the protein (PD) and the other half is unbound (D), then the concentration of PD is equal to that of D, $[\mathrm{PD}] = [\mathrm{D}]$, and the concentration of P ([P]) is equal to K_d. The lower the K_d, the tighter that P binds to D — often referred to as a higher binding affinity of P for D — and thus the lower the concentration of P needed to bind to half of D. This can sometimes lead to a bit of confusion. Remember, the *lower* the K_d, the *higher* the binding affinity, and the tighter the binding.

Typically, a protein's binding to a specific DNA sequence exhibits a K_d of 10^{-10} M, where M symbolizes molarity, or moles per liter ($\mathrm{mol/L}$). To relate the magnitude of this dissociation constant to the intracellular ratio of bound to unbound DNA, let's consider the simple example of a bacterial cell having a volume of 1.5×10^{-15} L and containing 1 molecule of DNA and 10 molecules of the DNA-

binding protein P. In this case, given a K_d of 10^{-10} M and the total concentration of the P in the cell (~111×10^{-10} M, about a hundredfold higher than the K_d), 99 percent of the time the specific DNA sequence to which P binds will have a molecule of protein P bound to it and 1 percent of the time it will not, even though the cell contains only 10 molecules of the protein! Clearly P and D have a high affinity for each other and bind tightly, as reflected by the low value of the dissociation constant for their binding. For protein-protein and protein-DNA binding, K_d values of ~10^{-9} M (nanomolar) or less are considered to be tight, ~10^{-6} M (micromolar) modestly tight, and ~10^{-3} M (millimolar) relatively weak.

A large biological macromolecule, such as a protein, can have multiple binding surfaces for binding several molecules simultaneously (Figure 2-24). In some cases, these binding reactions are independent, each with its own distinct K_d value that is independent of the others. In other cases, binding of a molecule at one site on a macromolecule can change the three-dimensional shape, or conformation, of a distant site (a phenomenon called **allostery**, see Chapter 3). That change in conformation alters the site's binding interactions with some other molecule (altering the K_d). The covalent modifications of amino acid side chains — mentioned previously — often influence the three-dimensional shapes of binding sites required for such binding interactions. These covalent and noncovalent binding reactions are important

mechanisms by which one molecule can alter, and thus regulate, the structure and binding activity of another. We examine this regulatory mechanism in more detail in Chapter 3.

FIGURE 2-24 Macromolecules can have distinct binding sites for multiple ligands. A large macromolecule (e.g., a protein, purple) with three distinct binding sites (yellow, A–C) is shown; each of the three binding sites exhibit molecular complementarity to three different binding partners (ligands A–C) with distinct dissociation constants ($K_{dA–C}$).

Biological Fluids Have Characteristic pH Values

The solvent inside cells and in all extracellular fluids is water. An important characteristic of any aqueous solution is the concentration of positively charged hydrogen ions (H^+) and negatively charged hydroxyl ions (OH^-). Because these ions are the dissociation products of H_2O, they are constituents of all living systems, and they are liberated by many reactions that take place between molecules within cells. These ions can also be transported into or out of cells, as when highly acidic gastric juice is secreted by cells lining the walls of the stomach.

When a water molecule dissociates, one of its polar H—O bonds breaks. The resulting hydrogen ion, referred to as a *proton*, has a short lifetime as a free ion and quickly combines with a water molecule to form a hydronium ion (H_3O^+). For convenience, we refer to the concentration of hydrogen ions in a solution, $[H^+]$, even though this quantity really represents the concentration of hydronium ions, $[H_3O^+]$. Dissociation of H_2O generates one OH^- ion along with each H^+. The dissociation of water is a reversible reaction:

$$H_2O \rightleftharpoons H^+ + OH^-$$

At 25 °C, $[H^+][OH^-] = 10^{-14}\ M^2$, so that in pure water, $[H^+] = [OH^-] = 10^{-7}$ M.

The concentration of hydrogen ions in a solution is expressed conventionally as its **pH**, defined as the negative log of the hydrogen ion concentration. The pH of pure water at 25 $^\circ$C is 7:

$$\mathrm{pH} = -\log[\mathrm{H}^+] = \log \frac{1}{[\mathrm{H}^+]} = \log \frac{1}{10^{-7}} = 7$$

It is important to keep in mind that a one-unit difference in pH represents a tenfold difference in the concentration of protons. On the pH scale, 7.0 is considered neutral: pH values below 7.0 indicate acidic solutions (higher $[\mathrm{H}^+]$), and values above 7.0 indicate basic, or alkaline, solutions (Figure 2-25). For instance, gastric juice, which is rich in hydrochloric acid (HCl), has a pH of about 1. Its $[\mathrm{H}^+]$ is roughly 1-million-fold greater than that of cytoplasm, which has a pH of about 7.2–7.4.

FIGURE 2-25 Some pH values for common solutions. The pH of an aqueous solution is the negative log of the hydrogen ion concentration. The pH values for most intracellular and extracellular biological fluids are near 7 and are

carefully regulated to permit the proper functioning of cells, organelles, and cellular secretions. The pH values for solutions of ammonia and hydrochloric acid are for one molar (1 M) solutions.

Although the cytosol of cells normally has a pH of about 7.2, the interior of certain organelles in eukaryotic cells (see Chapter 1) can have a much lower pH. The internal (luminal) fluid in lysosomes, for example, has a pH of about 4.5. The many degradative enzymes within lysosomes function optimally in an acidic environment, whereas their action is inhibited in the near neutral pH environment of the cytoplasm. As this example illustrates, maintenance of a particular pH is essential for the proper functioning of some cellular structures. On the other hand, dramatic shifts in cellular pH may play an important role in controlling cellular activity. For example, the pH of the cytoplasm of an unfertilized egg of the sea urchin, an aquatic animal, is 6.6. Within 1 minute of fertilization, however, the pH rises to 7.2; that is, the $[H^+]$ decreases to about one-fourth its original value, a change that is necessary for subsequent growth and division of the egg.

Hydrogen Ions Are Released by Acids and Taken Up by Bases

In general, an **acid** is any molecule, ion, or chemical group that tends to release a hydrogen ion (H^+). Examples are the carboxyl

group (—COOH), which tends to dissociate to form the negatively charged carboxylate ion ($—COO^-$) and a hydrogen ion, and hydrochloric acid (HCl). Conversely, a **base** is any molecule, ion, or chemical group that readily combines with an H^+. Examples are the hydroxyl ion (OH^-); ammonia (NH_3), which forms an ammonium ion ($NH_4{}^+$); and the amino group ($—NH_2$).

When an acid is added to an aqueous solution, the $[H^+]$ increases, and the pH goes down. Conversely, when a base is added to an aqueous solution, the $[H^+]$ decreases, and the pH goes up. Because $[H^+][OH^-] = 10^{-14}\ M^2$, any increase in $[H^+]$ is coupled with a commensurate decrease in $[OH^-]$, and vice versa.

Many biological molecules contain both acidic and basic groups. For example, in neutral solutions ($pH = 7.0$), many amino acids exist predominantly in the doubly ionized form, in which the carboxyl group has lost a proton and the amino group has accepted one:

where R represents the uncharged side chain. Such a molecule, containing an equal number of positive and negative ions, is called a

zwitterion. Zwitterions, having no net charge, are neutral. At extreme pH values, only one of these two ionizable groups of an amino acid is charged: the $—NH_2{}^+$ at low pH or the $—COO^-$ at high pH.

The dissociation reaction for an acid (or acid group in a larger molecule), HA, can be written as $HA \rightleftharpoons H^+ + A^-$. The equilibrium constant for this reaction, denoted K_a (the subscript *a* stands for "acid"), is defined as $K_a = [H^+][A^-]/[HA]$. Taking the logarithm of both sides and rearranging the result yields a very useful relation between the equilibrium constant K_a and pH:

$$pH = pK_a + \log \frac{[A^-]}{[HA]} \tag{2-5}$$

where pK_a equals $-\log\ K_a$.

From this expression, commonly known as the *Henderson–Hasselbalch equation*, it can be seen that the pK_a of any acid is equal to the pH at which half the molecules are dissociated and half are neutral (undissociated). This is because when $[A^-] = [HA]$, then $\log\ ([A^-]/[HA]) = 0$, and thus $pK_a\ = PH$. The Henderson–Hasselbalch equation allows us to calculate the degree of dissociation of an acid — that is, the ratio of dissociated and undissociated forms — if both the pH of the solution and the pK_a of

the acid are known. Experimentally, by measuring the $[A^-]$ and $[HA]$ as a function of the solution's pH, one can calculate the pK_a of the acid and thus the equilibrium constant K_a for the dissociation reaction (Figure 2-26). Knowing the pK_a of a molecule not only provides an important description of its properties, but also allows us to exploit these properties to manipulate the acidity of an aqueous solution and to understand how biological systems control this critical characteristic of their aqueous fluids.

FIGURE 2-26 The relationship between pH, pK_a, and the dissociation of an acid. As the pH of a solution of carbonic acid rises from 0 to 8.5, the percentage of the compound in the undissociated, or un-ionized, form (H_2CO_3) decreases from 100 percent and that of the

ionized form increases from 0 percent. When the pH (6.4) is equal to the acid's $\mathrm{p}K_a$, half of the carbonic acid has ionized. When the pH rises to above 8, virtually all of the acid has ionized to the bicarbonate form $(\mathrm{HCO_3}^-)$.

Buffers Maintain the pH of Intracellular and Extracellular Fluids

A living, actively metabolizing cell must maintain a constant pH in the cytoplasm of about 7.2–7.4, and it must do so even as its metabolism is producing many acids. Cells have a reservoir of weak bases and weak acids, called **buffers**, which ensure that the cell's cytoplasmic pH remains relatively constant despite small fluctuations in the amounts of H^+ or OH^- being generated by metabolism or by the uptake or secretion of molecules and ions by the cell. Buffers maintain a constant pH by soaking up excess H^+ or OH^- when these ions are added to the cell or are produced by metabolism. As we shall see, buffers are most effective at preventing changes in pH when the pH of the solution is similar to the $\mathrm{p}K_\mathrm{a}$ of the buffer.

Consider a buffered solution whose pH is equal to the $\mathrm{p}K_\mathrm{a}$ of the buffer $([\mathrm{HA}] = [\mathrm{A}^-])$. If additional acid (or base) is added to this solution, the pH of the solution changes, but it changes less than it would if the buffer had not been present. This is because protons released by the added acid are taken up by the ionized form of the

buffer (A^-); likewise, hydroxyl ions released by the added base are neutralized by protons released by the undissociated buffer (HA). The capacity of a buffer or any other substance to release hydrogen ions or take them up depends partly on the extent to which the substance has already taken up or released protons, which in turn depends on the pH of the solution relative to the pK_a of the substance. The ability of a buffer to minimize changes in pH, its *buffering capacity*, depends on the concentration of the buffer and the relationship between its pK_a value and the pH, which is expressed by the Henderson–Hasselbalch equation.

The titration curve for acetic acid shown in Figure 2-27 illustrates the effect of pH on the fraction of molecules in the un-ionized (HA) and ionized (A^-) forms. When the pH is equal to the pK_a, half of the acetic acid is dissociated (dashed lines). At one pH unit below the pK_a of an acid, 91 percent of the molecules are in the HA form; at one pH unit above the pK_a, 91 percent are in the A^- form. At pH values more than one unit above or below the pK_a (unshaded regions in Figure 2-27), the buffering capacity of weak acids and bases declines rapidly. In other words, the addition of the same number of moles of base — for example, hydroxyl ions added as sodium hydroxide (NaOH) — to a solution containing a mixture of HA and A^- that is at a pH near the pK_a will cause less of a pH change than it would if the HA and A^- were not present or if the pH were far from the pK_a value.

FIGURE 2-27 The titration curve of the buffer acetic acid (CH_3COOH). The pK_a for the dissociation of acetic acid to hydrogen and acetate ions is 4.75. At this pH, half the acetic acid molecules are dissociated. Because pH is measured on a logarithmic scale, the solution changes from 91 percent CH_3COOH at pH 3.75 to 9 percent CH_3COOH at pH 5.75. The acid has maximum buffering capacity in this pH range.

All biological systems contain one or more buffers. Phosphate ions, the ionized forms of phosphoric acid, are present in considerable quantities in cells and are an important buffer in maintaining, or buffering, the pH of the cytoplasm. Phosphoric acid (H_3PO_4) has three protons that are capable of dissociating, but they do not dissociate simultaneously. Loss of each proton can be described by a

discrete dissociation reaction and pK_a, as shown in Figure 2-28. When hydroxyl ions are added to a solution of phosphoric acid, the pH change is much less steep at pH values near the three pK_a values (shaded regions) than when the pH of the solution is not similar to any of the pK_as. The titration curve for phosphoric acid shows that the pK_a for the dissociation of the second proton is 7.2. Thus at pH 7.2, about 50 percent of cellular phosphate is $H_2PO_4^-$ and about 50 percent is HPO_4^{2-} according to the Henderson–Hasselbalch equation. For this reason, phosphate is an excellent buffer at pH values around 7.2, the approximate pH of the cytoplasm of cells, and at pH 7.4, the pH of human blood. The amino (lysine), guanidinium (arginine), and carboxylate (aspartate, glutamate) portions of amino acid side chains of proteins as well as the amino and carboxylate groups at the N- and C-termini of proteins can also bind and release protons. Thus proteins that are present in high concentrations inside cells and in many extracellular fluids can themselves serve as buffers.

FIGURE 2-28 The titration curve of phosphoric acid (H_3PO_4), a common buffer in biological systems. This biologically ubiquitous molecule has three hydrogen atoms that dissociate at different pH values; thus phosphoric acid has three pK_a values, as noted on the graph. The shaded areas denote the pH ranges — within one pH unit of the three pK_a values — where the buffering capacity of phosphoric acid is high. In these regions, the addition of an acid (or base) will cause relatively small changes in the pH.

KEY CONCEPTS OF SECTION 2.3

Chemical Reactions and Chemical Equilibrium

- A chemical reaction is at equilibrium when the rate of the forward reaction is equal to the rate of the reverse reaction, and thus there is no net change over time in the concentration of the reactants or products.

- The equilibrium constant K_{eq} of a reaction reflects the ratio of products to reactants at equilibrium and thus is a measure of the extent of the reaction and the relative stabilities of the reactants and products.
- The K_{eq} depends on the temperature, pressure, and chemical properties of the reactants and products but is independent of the reaction rate and of the initial concentrations of reactants and products.
- For any reaction, the equilibrium constant K_{eq} equals the ratio of the forward rate constant to the reverse rate constant (k_{f}/k_r). The rates of conversion of reactants to products and vice versa depend on the rate constants and the concentrations of the reactants or products.
- Within cells, the linked reactions in metabolic pathways generally are not at equilibrium, but rather at steady state, at which the rate of formation of the intermediates equals their rate of consumption (see Figure 2-23), and thus the concentrations of the intermediates are not changing.
- The dissociation constant K_{d} for the noncovalent binding of two molecules is a measure of the tightness of binding or the stability of the complex formed between the molecules (e.g., ligand-receptor or protein-DNA complexes). The *lower* the K_d, the *higher* the binding affinity, and the tighter the binding. K_{d} values of ~$10^{-9}\ \mathrm{M}$ (nanomolar) are considered to be tight, ~$10^{-6}\ \mathrm{M}$ (micromolar) modestly tight, and ~$10^{-3}\ \mathrm{M}$ (millimolar) relatively weak.
- The pH is the negative logarithm of the concentration of hydrogen ions $(-\log\ [\mathrm{H}^+])$. The pH of the cytoplasm is normally about 7.2–7.4, whereas the interior of lysosomes has a pH of about 4.5.
- Acids release protons (H^+), and bases bind them.
- Buffers are mixtures of a weak acid (HA) and its corresponding base form (A^-), which minimize the change in pH of a solution when an acid or base is added. Biological systems use various buffers to maintain their pH within a very narrow range to permit the optimal functioning of biomolecules.

2.4 Biochemical Energetics

Obtaining, storing, and using energy are central to cellular life. Energy may be defined as the ability to do work, a concept that is as applicable to cells as to automobile engines and electric power plants. The energy stored within chemical bonds can be harnessed to support chemical work and the physical movements of cells. In this section, we review how energy influences the extents of chemical reactions (chemical thermodynamics) and the rates of chemical reactions (chemical kinetics).

Several Forms of Energy Are Important in Biological Systems

There are two principal forms of energy: kinetic and potential. **Kinetic energy** is the energy of movement — the motion of molecules, for example. **Potential energy** is stored energy — the energy stored in covalent bonds, for example. Potential energy plays a particularly important role in the energy economy of cells.

Thermal energy, or heat, is a form of kinetic energy — the energy of the motion of molecules. For heat to do work, it must flow from a region of higher temperature, where the average speed of molecular motion is greater, to one of lower temperature. Although differences in temperature can exist between the internal and external

environments of cells, these thermal gradients do not usually serve as the source of energy for cellular activities. The thermal energy in warm-blooded animals, which have evolved a mechanism for thermoregulation, is used chiefly to maintain constant body temperature. This is an important homeostatic function because the rates of many cellular activities are temperature dependent. For example, cooling mammalian cells from their normal body temperature of 37 °C to 4 °C can almost completely freeze or stop many cellular processes (e.g., intracellular membrane movements). Overheating can be lethal because heat disrupts the noncovalent interactions that are required to maintain the structures and functions of biological macromolecules and macromolecular complexes.

Radiant energy is the kinetic energy of photons, or waves of light. This form of kinetic energy is critical to biology. Radiant energy can be converted to thermal energy, for instance, when light is absorbed by molecules and the energy is converted to molecular motion. Radiant energy absorbed by molecules can also change the electronic structure of the molecules by moving electrons into higher energy orbitals, from whence the energy can later be recovered to perform work. For example, during photosynthesis, light energy absorbed by pigment molecules such as chlorophyll is subsequently converted into the energy of chemical bonds (see Chapter 12).

Mechanical energy, a major form of kinetic energy in biology, usually results from the conversion of stored chemical energy. For example, changes in the lengths of cytoskeletal filaments powered by chemical energy generate mechanical forces that push or pull on membranes and organelles (see Chapters 17 and 18).

Electric energy — the energy of moving electrons or other charged particles — is yet another major form of kinetic energy. Electric energy has particular importance to membrane function, as in electrically active neurons (see Chapters 11, 12, and 23).

Several forms of potential energy are biologically significant. Central to biology is **chemical potential energy**, the energy stored in the bonds connecting atoms in molecules. Indeed, most of the biochemical reactions described in this book involve the making or breaking of at least one covalent chemical bond. In general, energy must be expended to make covalent bonds in typical biomolecules, and energy is released when those bonds are broken. For example, the high potential energy in the covalent bonds of glucose can be released by controlled enzymatic combustion in cells (see Chapter 12). This energy is harnessed by the cell to do many kinds of work.

A second biologically important form of potential energy is the energy in a **concentration gradient**. When the concentration of a substance on one side of a barrier, such as a membrane, is different from that on the other side, a concentration gradient exists. All cells

form concentration gradients between their interior and the external fluids by selectively exchanging nutrients, waste products, and ions with their surroundings. Furthermore, the fluids within organelles in cells (e.g., mitochondria, lysosomes) frequently contain different concentrations of ions and other molecules than those in the cytosol; the concentration of protons within a lysosome (pH $\sim$4.5), as we saw in the last section, is about 500 times that in the cytosol (pH 7.2–7.4). Concentration gradients of protons across membranes are an important driver of energy production in mitochondria (see Chapter 12).

A third form of potential energy in cells is an **electric potential** — the energy of charge separation. For instance, there is a gradient of electric charge of about 200,000 volts per centimeter across the plasma membranes of virtually all cells. In Chapter 11, we discuss how concentration gradients and electric potential gradients are generated and maintained. In Chapter 12, we cover how they are converted to chemical potential energy.

Cells Can Transform One Type of Energy into Another

According to the first law of thermodynamics, energy is neither created nor destroyed, but can be converted from one form to another. (In nuclear reactions, mass is converted to energy, but this

is irrelevant in biological systems.) Energy conversions are very important in biology. In photosynthesis, for example, the radiant energy of light is transformed into the chemical potential energy of the covalent bonds between the atoms in a sucrose or starch molecule. In muscles and nerves, chemical potential energy stored in covalent bonds is transformed, respectively, into the kinetic energy of muscle contraction and the electric energy of neural transmission. In all cells, potential energy — released by breaking certain chemical bonds — is used to generate potential energy in the form of concentration and electric potential gradients. Similarly, energy stored in chemical concentration gradients or electric potential gradients is used to synthesize chemical bonds or to transport molecules from one side of a membrane to another to generate a concentration gradient. The latter process occurs during the transport of nutrients such as glucose into certain cells and the transport of many waste products out of cells.

Because all forms of energy are interconvertible, they can be expressed in the same units of measurement. Although the standard unit of energy is the joule, biochemists have traditionally used an alternative unit, the *calorie* ($1 \text{ joule} = 0.239 \text{ calorie}$). A calorie is the amount of energy required to raise the temperature of one gram of water by $1\ ^\circ\text{C}$. Throughout this book, we use the *kilocalorie* to measure energy changes ($1 \text{ kcal} = 1000 \text{ cal}$). When you read or hear about the "Calories" in food (note the capital *C*), the reference is almost always to kilocalories as defined here.

The Change in Free Energy Determines If a Chemical Reaction Will Occur Spontaneously

Chemical reactions can be divided into two types, depending on whether energy is absorbed or released in the process. In an **exergonic** ("energy-releasing") reaction, the products contain less energy than the reactants. Exergonic reactions take place spontaneously. The liberated energy is usually released as heat (the energy of molecular motion) and generally results in a rise in temperature, as in the oxidation (burning) of wood. In an **endergonic** ("energy-absorbing") reaction, the products contain more energy than the reactants, and energy is absorbed from the surroundings during the reaction. If there is no external source of energy to drive an endergonic reaction, it cannot take place. Endergonic reactions are responsible for the ability of the instant cold packs often used to treat injuries to rapidly cool below room temperature. Crushing the pack mixes the reactants, initiating the reaction.

A fundamentally important concept in understanding if a reaction is exergonic or endergonic, and therefore if it occurs spontaneously or not, is free energy (G), or *Gibbs free energy*, named after J. W. Gibbs. Gibbs, who received the first PhD in engineering in America in 1863, showed that "all systems change in such a way that free energy [*G*] is minimized." In other words, a chemical reaction occurs

spontaneously when the free energy of the products is lower than the free energy of the reactants. In the case of a chemical reaction, $\text{reactants} \rightleftharpoons \text{products}$, the **free-energy change, ΔG**, is given by

$$\Delta G = G_{\text{products}} - G_{\text{reactants}}$$

The relation of ΔG to the direction of any chemical reaction can be summarized in three statements:

- If ΔG is negative, the forward reaction (generation of products) will tend to occur spontaneously, and energy usually will be released as the reaction takes place (exergonic reaction) (Figure 2-29a). A reaction with a negative ΔG is referred to as thermodynamically favorable.
- If ΔG is positive, the forward reaction will not occur spontaneously; energy will have to be added to the system in order to force the reactants to become products (endergonic reaction, Figure 2-29b).
- If ΔG is zero, both forward and reverse reactions will occur without a gain or loss of energy, and there will be no spontaneous net conversion of reactants to products, or vice versa; the system is at equilibrium.

FIGURE 2-29 Changes in the free energy (ΔG) of exergonic and endergonic reactions. (a) In exergonic reactions, the free energy of the products is less than that of the reactants. Consequently, these reactions occur spontaneously, and energy is released as the reactions proceed. (b) In endergonic reactions, the free energy of the products is greater than that of the reactants, and these reactions do not occur spontaneously. An external source of energy must be supplied if the reactants are to be converted into products.

By convention, the *standard free-energy change* of a reaction ($\Delta G^{\circ\prime}$) is the value of the change in free energy at 298 K (25 °C), 1 atm pressure, pH 7.0 (as in pure water), and initial concentrations of 1 M for all reactants and products except protons, which are kept at 10^{-7}M (pH 7.0). The conditions of most biological reactions differ from these standard conditions, particularly in the concentrations

of reactants, which are normally less than 1 M, and in the temperature of mammals (37 °C).

The free energy of a chemical system can be defined as $G = H - TS$, where H is the bond energy, or **enthalpy (*H*)**, of the system; T is its temperature in degrees Kelvin (K); and S is the **entropy (*S*)**, a measure of its randomness or disorder. According to the second law of thermodynamics, the natural tendency of any isolated system is to become more disordered — that is, for entropy to increase. For example, a drop of ink placed in a large container of water will spontaneously spread out (become less ordered) rather than remain in a concentrated drop in the container. A reaction can occur spontaneously only if the combined effects of changes in enthalpy and entropy lead to a lower ΔG. That is, if temperature remains constant, a reaction proceeds spontaneously only if the free-energy change, ΔG, in the following equation is negative:

$$\Delta G = \Delta H - T\Delta S \tag{2-6}$$

In an **exothermic** ("heat-releasing") chemical reaction, ΔH is negative. In an **endothermic** ("heat-absorbing") reaction, ΔH is positive. The combined effects of the changes in the enthalpy and entropy determine if the ΔG for a reaction is positive or negative and thus if the reaction occurs spontaneously. An exothermic reaction ($\Delta H < 0$) in which entropy increases ($\Delta S > 0$) occurs

spontaneously ($\Delta G < 0$). An endothermic reaction ($\Delta H > 0$) will occur spontaneously if ΔS increases enough so that the $T\Delta S$ term can overcome the positive ΔH.

Many biological reactions lead to an increase in order and thus a decrease in entropy ($\Delta S < 0$). An obvious example is the reaction that links amino acids to form a protein. A solution of protein molecules has a lower entropy than does a solution of the same amino acids unlinked because the free movement of any amino acid is more restricted (greater order) when it is bound into a long chain than when it is not. Thus when cells synthesize polymers such as proteins from their constituent monomers, the polymerizing reaction will be spontaneous only if the cells can efficiently transfer energy to both generate the bonds that hold the monomers together and overcome the loss in entropy that accompanies polymerization. Often cells accomplish this feat by *coupling* such synthetic, entropy-lowering reactions with independent reactions that have a very highly negative ΔG, such as the hydrolysis of nucleoside triphosphates (discussed later in this section). In this way, cells can convert sources of energy in their environment into the highly organized structures and metabolic pathways that are essential for life.

The actual change in free energy during a reaction is influenced by temperature, pressure, and the initial concentrations of reactants and products, so it usually differs from the standard free-energy

change $\Delta G^{\circ\prime}$. Most biological reactions — like others that take place in aqueous solutions — are also affected by the pH of the solution. We can estimate free-energy changes for temperatures and initial concentrations that differ from the standard conditions by using the equation

$$\Delta G = \Delta G^{\circ\prime} + RT \ln Q = \Delta G^{\circ\prime} + RT \ln \frac{[\text{products}]}{[\text{reactants}]} \tag{2-7}$$

where R is the gas constant of $1.987\ \text{cal}/(\text{degree}\cdot\text{mol})$, T is the temperature (in degrees Kelvin), and Q is the *initial* ratio of products to reactants. For a reaction $\text{A} + \text{B} \rightleftharpoons \text{C}$, in which two molecules combine to form a third, Q in Equation 2-7 equals $[\text{C}]/[\text{A}][\text{B}]$. In this case, an increase in the initial concentration of either $[\text{A}]$ or $[\text{B}]$ will result in a larger negative value for ΔG and thus drive the reaction toward spontaneous formation of C.

Regardless of the $\Delta G^{\circ\prime}$ of a particular biochemical reaction, it will proceed spontaneously within cells only if ΔG is negative given the intracellular concentrations of reactants and products. For example, the conversion of glyceraldehyde 3-phosphate (G3P) to dihydroxyacetone phosphate (DHAP), two intermediates in the cellular breakdown of glucose (see Chapter 12),

$$\text{G3P} \rightleftharpoons \text{DHAP}$$

has a $\Delta G^{\circ\prime}$ of -1840 cal/mol. If the initial concentrations of G3P and DHAP are equal, then $\Delta G = \Delta G^{\circ\prime}$ because $RT\ \ln[\text{products}]/[\text{reactants}] = 0$; in this situation, the reversible reaction G3P $\rightleftharpoons$ DHAP will proceed spontaneously in the direction of DHAP formation until equilibrium is reached. However, if the initial [DHAP] is 0.1 M and the initial [G3P] is 0.001 M, with other conditions standard, then Q in Equation 2-7 equals $0.1/0.001 = 100$, giving a ΔG of $+887$ cal/mol. Under these conditions, the reaction will proceed in the direction of formation of G3P.

The ΔG of a reaction is independent of the reaction rate. Indeed, under normal physiological conditions, few, if any, of the biochemical reactions needed to sustain life would occur quickly enough without some mechanism for increasing reaction rates. As we describe below and in more detail in Chapter 3, the rates of reactions in biological systems are usually determined by the activity of **enzymes**, the protein catalysts that accelerate the formation of products from reactants without altering the value of ΔG.

The $\Delta G^{\circ\prime}$ of a Reaction Can Be Calculated from Its K_{eq}

A chemical mixture at equilibrium is in a stable state of minimal free energy. For a system at equilibrium ($\Delta G = 0, Q = K_{\text{eq}}$) under standard conditions, we can write

$$\Delta G^{\circ\prime} = -2.3RT \ \log K_{\text{eq}} = -1362 \ \log K_{\text{eq}} \tag{2-8}$$

(note the change to base 10 logarithms). Thus if we determine the concentrations of reactants and products at equilibrium (i.e., the K_{eq}), we can calculate the value of $\Delta G^{\circ\prime}$. For example, the K_{eq} for the interconversion of glyceraldehyde 3-phosphate to dihydroxyacetone phosphate (G3P $\rightleftharpoons$ DHAP) is 22.2 under standard conditions. Substituting this value into Equation 2-8, we can easily calculate the $\Delta G^{\circ\prime}$ for this reaction as -1840 cal/mol.

By rearranging Equation 2-8 and taking the antilogarithm, we obtain

$$K_{\text{eq}} = 10^{-(\Delta G^{\circ\prime}/2.3RT)} \tag{2-9}$$

From this expression, it is clear that if $\Delta G^{\circ\prime}$ is negative, the exponent will be positive, and hence K_{eq} will be greater than 1. Therefore, at equilibrium there will be more products than reactants; in other words, the formation of products from reactants is favored. Conversely, if $\Delta G^{\circ\prime}$ is positive, the exponent will be negative, and K_{eq} will be less than 1. The relationship between K_{eq}

and $\Delta G^{\circ\prime}$ further emphasizes the influence of the relative free energies of reactants and products on the extent to which a reaction will occur spontaneously.

The Rate of a Reaction Depends on the Activation Energy Necessary to Energize the Reactants into a Transition State

As a chemical reaction proceeds, reactants approach each other; some bonds begin to form while others begin to break. One way to think of the state of the molecules during this transition is that there are strains in the electronic configurations of the atoms and their bonds. The collection of atoms moves from the relatively stable state of the reactants to a transient, intermediate, and higher energy state during the course of the reaction (Figure 2-30). The state during a chemical reaction at which the system is at its highest energy level is called the **transition state**, and the collection of reactants in that state is called the **transition-state intermediate**. The energy needed to excite the reactants to this higher energy state is called the **activation energy** of the reaction. The activation energy is the difference in free energy between the reactants and the transition-state intermediate. The activation energy is usually represented by $\Delta G^{\ddagger}$, which is analogous to the representation of the change in Gibbs free energy (ΔG) already discussed. From the transition state,

the collection of atoms can either release energy as the reaction products are formed (reaction proceeds to the right in Figure 2-30) or release energy as the atoms go backward (leftward in Figure 2-30) and re-form the original reactants.

FIGURE 2-30 Activation energy of uncatalyzed and catalyzed chemical reactions. This hypothetical reaction pathway (blue) depicts the changes in free energy, *G*, as a reaction proceeds. A reaction will take place spontaneously if the free energy (*G*) of the products is less than that of the reactants ($\Delta G < 0$). However, all chemical reactions proceed through one (shown here) or more high-energy transition states, and the rate of a reaction is inversely proportional to the activation energy ($\Delta G^{\ddagger}$), which is the difference in free energy between the reactants and the transition state. In a catalyzed reaction (red), the free energies of the reactants and products are unchanged, but the free energy of the transition state is lowered, thus increasing the velocity of the reaction.

The velocity (V) at which products are generated from reactants during the reaction under a given set of conditions (temperature, pressure, reactant concentrations) will depend on the concentration of material in the transition state. That concentration will depend on (1) the rate at which reactants are converted into the transition state, which depends on the activation energy, and (2) the characteristic rate constant (v) at which the material in the transition state is converted to products. The higher the activation energy, the lower the fraction of reactants that reach the transition state, and the slower the overall rate of the reaction. The relationship between the concentration of reactants, v, and V is

$$V = v\,[\text{reactants}] \times 10^{-(\Delta G^{\ddagger}/2.3\text{RT})}$$

From this equation, we can see that lowering the activation energy $\Delta G^{\ddagger}$ — that is, decreasing the difference in free energy between the reactants and the transition state — leads to an acceleration of the overall reaction rate V. A reduction in $\Delta G^{\ddagger}$ of $1.36\ \text{kcal/mol}$ leads to a tenfold increase in the rate of the reaction, whereas a $2.72\ \text{kcal/mol}$ reduction increases the rate a hundredfold. Thus relatively small changes in $\Delta G^{\ddagger}$ can lead to large changes in the overall rate of the reaction.

Catalysts such as enzymes (discussed further in Chapter 3) accelerate reaction rates by lowering the relative energy of the transition state and thus the activation energy required to reach it

(see Figure 2-30). The relative energies of reactants and products determine if a reaction is thermodynamically favorable (negative ΔG), whereas the activation energy determines how rapidly products form — that is, the reaction kinetics. Thermodynamically favorable reactions will not occur at appreciable rates if the activation energies are too high.

Life Depends on the Coupling of Energetically Unfavorable Chemical Reactions with Energetically Favorable Ones

Many processes in cells are energetically unfavorable ($\Delta G > 0$) and will not proceed spontaneously. Examples include the synthesis of proteins from amino acids and the transport of a substance across the plasma membrane from a lower to a higher concentration. Cells can carry out an energy-requiring, or endergonic, reaction ($\Delta G_1 > 0$) by coupling it to an energy-releasing, or exergonic, reaction ($\Delta G_2 < 0$) if the sum of the two reactions has an overall net negative ΔG.

Suppose, for example, that the reaction $\mathrm{A} \rightleftharpoons \mathrm{B} + \mathrm{X}$ has a ΔG of $+5\ \mathrm{kcal/mol}$ and that the reaction $\mathrm{X} \rightleftharpoons \mathrm{Y} + \mathrm{Z}$ has a ΔG of $-10\ \mathrm{kcal/mol}$:

$$
\begin{array}{lcccccl}
(1) & \mathrm{A} & \rightleftharpoons & \mathrm{B} + \mathrm{X} & \Delta G & = +5\ \mathrm{kcal/mol} \\
(2) & \mathrm{X} & \rightleftharpoons & \mathrm{Y} + \mathrm{Z} & \Delta G & = -10\ \mathrm{kcal/mol} \\
\hline
Sum: & \mathrm{A} & \rightleftharpoons & \mathrm{B} + \mathrm{Y} + \mathrm{Z} & \Delta G^{\circ\prime} & = -5\ \mathrm{kcal/mol}
\end{array}
$$

In the absence of the second reaction, there would be much more A than B at equilibrium. However, because the conversion of X to $\mathrm{Y} + \mathrm{Z}$ is such a favorable reaction, it will pull the first process toward the formation of B and the consumption of A. Energetically unfavorable reactions in cells are often coupled to the energy-releasing hydrolysis of ATP.

Hydrolysis of ATP Releases Substantial Free Energy and Drives Many Cellular Processes

In almost all organisms, the nucleoside triphosphate **adenosine triphosphate**, or **ATP** (Figures 2-1d and 2-31), is the most important molecule for capturing, transiently storing, and subsequently transferring energy to perform work such as biosynthesis or mechanical motion. Commonly referred to as a cell's energy *currency*, ATP is a type of usable potential energy that cells can *spend* in order to power their activities. The storied history of ATP begins with its discovery in 1929, apparently simultaneously by Kurt Lohmann, who was working with the famous biochemist Otto

Meyerhof in Germany and who published first, and by the less well-known Cyrus Fiske and Yellapragada SubbaRow in the United States. [It is noteworthy that SubbaRow, who died in 1948 at the age of 53, also made key contributions to treatments for major diseases, including anemia (folic acid), cancer and rheumatoid arthritis (methotrexate), and bacterial infections (first tetracycline antibiotic).] Muscle contractions were shown to depend on ATP in the 1930s. The proposal that ATP is the main intermediary for the transfer of energy in cells is credited to Fritz Lipmann around 1941. Many Nobel Prizes have been awarded for the study of ATP and its role in cellular-energy metabolism, and its importance in understanding molecular cell biology cannot be overstated.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 2-31 Hydrolysis of adenosine triphosphate (ATP). The two phosphoanhydride bonds (red) in ATP (*top*), which link the three phosphate groups, each have a $\Delta G^{\circ\prime}$ of about $-7.3\ \mathrm{kcal/mol}$ for hydrolysis. Hydrolysis of the terminal phosphoanhydride bond by the addition of water results in the release of phosphate and generation of ADP. Hydrolysis of the phosphoanhydride bonds of ATP is exergonic (Figure 2-29a), especially the terminal one, and the hydrolysis of these bonds is the source of energy that drives many energy-requiring reactions in biological systems.

The useful energy in an ATP molecule is contained in **phosphoanhydride bonds**. These are covalent bonds formed from the condensation of two molecules of phosphate by the loss of water:

As shown in Figure 2-31, an ATP molecule has two key phosphoanhydride (also called *phosphodiester*) bonds. Forming these bonds (represented here by the symbol ~) in ATP requires an input of energy. When these bonds are hydrolyzed, or broken by the addition of water, that energy is released. Hydrolysis of a phosphoanhydride bond in each of the following reactions has a highly negative $\Delta G^{\circ\prime}$ of about -7.3 kcal/mol:

$$\underset{\text{(ATP)}}{\text{Ap}\sim\text{p}\sim\text{p}} + \text{H}_2\text{O} \rightarrow \underset{\text{(ADP)}}{\text{Ap}\sim\text{p}} + \text{P}_\text{i} + \text{H}^+$$

$$\underset{\text{(ATP)}}{\text{Ap}\sim\text{p}\sim\text{p}} + \text{H}_2\text{O} \rightarrow \underset{\text{(AMP)}}{\text{Ap}} + \text{PP}_\text{i} + \text{H}^+$$

$$\underset{\text{(ADP)}}{\text{Ap}\sim\text{p}} + \text{H}_2\text{O} \rightarrow \underset{\text{(AMP)}}{\text{Ap}} + \text{P}_\text{i} + \text{H}^+$$

P_i stands for inorganic phosphate (PO_4^{3-}) and PP_i for inorganic pyrophosphate, two phosphate groups linked by a phosphoanhydride bond. As the top two reactions show, the removal of a phosphate group from ATP leaves adenosine diphosphate (ADP), and the removal of a pyrophosphate group from ATP leaves adenosine monophosphate (AMP).

A phosphoanhydride bond or other *high-energy bond* (commonly denoted by ~) is not intrinsically different from other covalent bonds. High-energy bonds simply release substantial amounts of energy when hydrolyzed. For instance, the $\Delta G^{\circ\prime}$ for hydrolysis of a phosphoanhydride bond in ATP (–7.3 kcal/mol) is more than three times the $\Delta G^{\circ\prime}$ for hydrolysis of the phosphoester bond (red) in glycerol 3-phosphate (–2.2 kcal/mol):

Glycerol 3-phosphate

A principal reason for this difference is that ATP and its hydrolysis products, ADP and P_i, are charged at neutral pH. During synthesis of ATP, a large amount of energy must be used to force the negative charges in ADP and P_i together. Conversely, this energy is released when ATP is hydrolyzed to ADP and P_i. In comparison, formation of the phosphoester bond between an uncharged hydroxyl in glycerol and P_i requires less energy, and less energy is released when this bond is hydrolyzed.

Cells have evolved mechanisms by which enzymes transfer the free energy released by hydrolysis of phosphoanhydride bonds to other molecules, thereby driving reactions that would otherwise be energetically unfavorable. For example, if the ΔG for the reaction $B + C \rightarrow D$ is positive but less than the absolute value of the ΔG for hydrolysis of ATP, the reaction can be driven to the right by coupling it to hydrolysis of the terminal phosphoanhydride bond in ATP. In one common mechanism of such *energy coupling*, some of the

energy stored in this phosphoanhydride bond is transferred to one of the reactants (here, B) by the breaking of the bond in ATP and the formation of a covalent bond between the released phosphate group and that reactant. The phosphorylated intermediate generated in this way can then react with reactant C to form product $\mathrm{D} + \mathrm{P_i}$ in a reaction that has an overall negative ΔG:

$$\mathrm{B} + \mathrm{Ap\sim p\sim p} \rightarrow \mathrm{B\sim p} + \mathrm{Ap\sim p}$$
$$\mathrm{B\sim p} + \mathrm{C} \rightarrow \mathrm{D} + \mathrm{P_i}$$

The overall reaction

$$\mathrm{B} + \mathrm{C} + \mathrm{ATP} \rightleftharpoons \mathrm{D} + \mathrm{ADP} + \mathrm{P_i}$$

is energetically favorable ($\Delta G < 0$). Similarly, hydrolysis of GTP to GDP can provide energy to perform work, including the synthesis of ATP (see Chapter 12), but most often GTP hydrolysis is used to control cellular systems (e.g., protein synthesis, hormonal signaling) rather than as a source of energy (see Chapter 15).

An alternative mechanism of energy coupling is to use the energy released by ATP hydrolysis to change the conformation of a molecule to an *energy-rich* stressed state. In turn, the energy stored as conformational stress can be released as the molecule relaxes back into its unstressed conformation. If this relaxation process can

be coupled to another reaction, the released energy can be harnessed to drive cellular processes.

As with many biosynthetic reactions, transport of molecules into or out of the cell often has a positive ΔG and thus requires an input of energy to proceed. Such simple transport reactions do not *directly* involve the making or breaking of covalent bonds; thus their $\Delta G^{\circ\prime}$ is 0. In the case of a substance moving into a cell, Equation 2-7 becomes

$$\Delta G = RT \ln \frac{[\mathrm{C_{in}}]}{[\mathrm{C_{out}}]} \tag{2-10}$$

where $[\mathrm{C_{in}}]$ is the initial concentration of the substance inside the cell and $[\mathrm{C_{out}}]$ is its concentration outside the cell. We can see from Equation 2-10 that ΔG is positive for transport of a substance into a cell against its concentration gradient (when $[\mathrm{C_{in}}] > [\mathrm{C_{out}}]$); the energy to drive such uphill transport is often supplied by the hydrolysis of ATP. Conversely, when a substance moves down its concentration gradient ($[\mathrm{C_{out}}] > [\mathrm{C_{in}}]$), ΔG is negative. Such downhill transport releases energy that can be coupled to an energy-requiring reaction, such as the movement of another substance uphill across a membrane or the synthesis of ATP itself (see Chapters 11 and 12).

ATP Is Generated During Photosynthesis and Respiration

ATP is continuously being hydrolyzed to provide energy for many cellular activities. Some estimates suggest that humans daily hydrolyze a mass of ATP equal to their entire body weight. Clearly to continue functioning, cells must constantly replenish their ATP supply. Therefore, cells must obtain energy from their environment that can be used to resynthesize the ATP. For nearly all cells, the ultimate source of energy used to make ATP is sunlight.

Some organisms can use sunlight directly. Through the process of **photosynthesis**, plants, algae, and certain photosynthetic bacteria trap the energy of sunlight and use it to synthesize ATP from ADP and P_i. Much of the ATP produced in photosynthesis is hydrolyzed to provide energy for the conversion of carbon dioxide to six-carbon sugars, a process called *carbon fixation*:

$$6\ CO_2 + 6\ H_2O \rightarrow C_6H_{12}O_6 + 6\ O_2 + \text{energy}$$

The sugars made during photosynthesis are a source of food, and thus energy, for the photosynthetic organisms making them and for the non-photosynthetic organisms, such as animals, that consume the plants either directly or indirectly by eating other animals that have eaten the plants. In this way, sunlight is the direct or indirect source of energy for most organisms (see Chapter 12).

In plants, animals, and nearly all other organisms, the free energy in sugars and other molecules derived from food is released in the processes of **glycolysis** and **cellular respiration**. During cellular respiration, energy-rich molecules in food (e.g., glucose) are oxidized to carbon dioxide and water. The complete oxidation of glucose,

$$\mathrm{C_6H_{12}O_6 + 6\ O_2 \rightarrow 6\ CO_2 + 6\ H_2O}$$

has a $\Delta G^{\circ\prime}$ of -686 kcal/mol and is the reverse of photosynthetic carbon fixation. Cells employ an elaborate set of protein-mediated reactions to couple the oxidation of 1 molecule of glucose to the synthesis of as many as 30 molecules of ATP from 30 molecules of ADP. This oxygen-dependent (**aerobic**) degradation (**catabolism**) of glucose is the major pathway for generating ATP in all animal cells, all non-photosynthetic plant cells, and many bacterial cells. Catabolism of fatty acids can also be an important source of ATP. We discuss the mechanisms of photosynthesis and cellular respiration in Chapter 12.

Although light energy captured in photosynthesis is the primary source of chemical energy for cells, it is not the only source. Certain microorganisms that live in or around deep-sea hydrothermal vents, where adequate sunlight is unavailable, derive the energy for converting ADP and $\mathrm{P_i}$ into ATP from the oxidation of reduced

inorganic compounds. These reduced compounds originate deep in the earth and are released at the vents.

NAD^+ and FAD Couple Many Biological Oxidation and Reduction Reactions

In many chemical reactions, electrons are transferred from one atom or molecule to another; this transfer may or may not accompany the formation of new chemical bonds or the release of energy that can be coupled to other reactions. The loss of electrons from an atom or a molecule is called **oxidation**, and the gain of electrons by an atom or a molecule is called **reduction**. An example of oxidation is the removal of electrons from the sulfhydryl group–containing side chains of two cysteine amino acids to form a disulfide bond, described in Section 2.2. Electrons are neither created nor destroyed in a chemical reaction, so if one atom or molecule is oxidized, another must be reduced. For example, oxygen draws electrons from Fe^{2+} (ferrous) ions to form Fe^{3+} (ferric) ions, a reaction that occurs as part of the process by which carbohydrates are degraded in mitochondria. Each oxygen atom receives two electrons, one from each of two Fe^{2+} ions:

$$2\,Fe^{2+} + \frac{1}{2}\,O_2 \rightarrow 2\,Fe^{3+} + O^{2-}$$

Thus Fe^{2+} is oxidized and O_2 is reduced. Such reactions in which one molecule is reduced and another is oxidized are often referred to as **redox reactions**. Oxygen is an electron acceptor in many redox reactions in cells under aerobic conditions.

Many biologically important oxidation and reduction reactions involve the removal or addition of hydrogen atoms (protons plus electrons) rather than the transfer of isolated electrons on their own. The oxidation of succinate to fumarate, which occurs in mitochondria, is an example (Figure 2-32). Protons are soluble in aqueous solutions (as H_3O^+), but electrons are not, so they must be transferred directly from one atom or molecule to another without a water-dissolved intermediate. In this type of oxidation reaction, electrons are often transferred to small, electron-carrying molecules, sometimes referred to as *coenzymes*. The most common of these electron carriers are **NAD^+ (nicotinamide adenine dinucleotide**), which is reduced to NADH, and **FAD (flavin adenine dinucleotide)**, which is reduced to $FADH_2$ (Figure 2-33). The reduced forms of these coenzymes can transfer protons and electrons to other molecules, thereby reducing them.

FIGURE 2-32 Conversion of succinate to fumarate. In this oxidation reaction, which occurs in mitochondria as part of the citric acid cycle, succinate loses two electrons and two protons. These protons and electrons are transferred to FAD, reducing it to $FADH_2$.

FIGURE 2-33 The electron-carrying coenzymes NAD^+ and FAD. (a) NAD^+ (nicotinamide adenine dinucleotide) is reduced to NADH by the addition of two electrons and one proton simultaneously. In many biological redox reactions, a pair of hydrogen atoms (two protons

and two electrons) is removed from a molecule. In some cases, one of the protons and both electrons are transferred to NAD^+; the other proton is released into solution. (b) FAD (flavin adenine dinucleotide) is reduced to $FADH_2$ by the addition of two electrons and two protons, as occurs when succinate is converted to fumarate (see Figure 2-32). In this two-step reaction, addition of one electron together with one proton first generates a short-lived semiquinone intermediate (not shown), which then accepts a second electron and proton.

To describe redox reactions, such as the reaction of ferrous ion (Fe^{2+}) and oxygen (O_2), it is easiest to divide them into two half-reactions:

$$\begin{aligned} \textit{Oxidation of } Fe^{2+}: &\quad 2\,Fe^{2+} \rightarrow 2\,Fe^{3+} + 2\,e^- \\ \textit{Reduction of } O_2: &\quad 2\,e^- + \frac{1}{2}\,O_2 \rightarrow O^{2-} \end{aligned}$$

In this case, the reduced oxygen (O^{2-}) readily reacts with two protons to form one water molecule (H_2O). The readiness with which an atom or a molecule *gains* an electron is its **reduction potential (*E*)**. The tendency to *lose* electrons, the **oxidation potential**, has the same magnitude as the reduction potential for the reverse reaction, but has the opposite sign.

Reduction potentials are measured in volts (V) from an arbitrary zero point set at the reduction potential of the following half-reaction under standard conditions (25 °C, 1 atm, and reactants at 1 M):

$$\mathrm{H^+ + e^-} \underset{\text{oxidation}}{\overset{\text{reduction}}{\rightleftharpoons}} \frac{1}{2}\,\mathrm{H_2}$$

The value of the reduction potential (E) for a molecule or an atom under standard conditions is its standard reduction potential, E'_0. A molecule or an ion with a positive E'_0 has a higher affinity for electrons than the $\mathrm{H^+}$ ion does under standard conditions. Conversely, a molecule or ion with a negative E'_0 has a lower affinity for electrons than the $\mathrm{H^+}$ ion does under standard conditions. Like the values of $\Delta G^{\circ\prime}$, standard reduction potentials may differ somewhat from those found under the conditions in a cell because the concentrations of reactants in a cell are not 1 M.

In a redox reaction, electrons move spontaneously toward atoms or molecules having *more positive* reduction potentials. In other words, a molecule having a more negative reduction potential can transfer electrons spontaneously to, or reduce, a molecule with a more positive reduction potential. In this type of reaction, the change in electric potential ΔE is the sum of the reduction and oxidation potentials for the two half-reactions. The ΔE for a redox reaction is related to the change in free energy ΔG by the following expression:

$$\Delta G\ (\mathrm{cal/mol}) = -n\ (23{,}064)\ \Delta E\ (\mathrm{volts}) \tag{2-11}$$

where n is the number of electrons transferred. Note that a redox reaction with a positive ΔE value will have a negative ΔG and thus will tend to proceed spontaneously from left to right.

KEY CONCEPTS OF SECTION 2.4

Biochemical Energetics

- The change in free energy, ΔG, is the most useful measure for predicting the potential of chemical reactions to occur spontaneously in biological systems. Chemical reactions tend to proceed spontaneously in the direction for which ΔG is negative. The magnitude of ΔG is independent of the reaction rate. A reaction with a negative ΔG is referred to as thermodynamically favorable.
- The chemical free-energy change, $\Delta G^{\circ\prime}$, equals $-2.3\ RT \log K_{\text{eq}}$. Thus the value of $\Delta G^{\circ\prime}$ can be calculated from the experimentally determined concentrations of reactants and products at equilibrium.
- The rate of a reaction depends on the activation energy needed to energize reactants to a transition state. Catalysts such as enzymes speed up reactions by lowering the activation energy of the transition state.
- A chemical reaction having a positive ΔG can proceed spontaneously if it is coupled with a reaction having a negative ΔG of larger magnitude.
- Many otherwise energetically unfavorable cellular processes are driven by the hydrolysis of phosphoanhydride bonds in ATP (see Figure 2-31).
- Directly or indirectly, light energy captured by photosynthesis in plants, algae, and photosynthetic bacteria is the ultimate source of chemical energy for nearly all cells on Earth.
- An oxidation reaction (loss of electrons) is always coupled with a reduction reaction (gain of electrons).
- Biological oxidation and reduction reactions are often coupled by electron-carrying coenzymes such as NAD^+ and FAD (see Figure 2-33).
- Oxidation-reduction reactions with a positive ΔE have a negative ΔG and thus tend to proceed spontaneously.

Review the Concepts

1. The gecko is a reptile with an amazing ability to climb smooth surfaces, including glass. Geckos appear to stick to smooth surfaces via van der Waals interactions between septa on their feet and the smooth surface. How is this method of stickiness advantageous over covalent interactions? Given that van der Waals forces are among the weakest molecular interactions, how can the gecko's feet stick so effectively?
2. The K^+ channel is an example of a transmembrane protein (a protein that spans the phospholipid bilayer of the plasma membrane). What types of amino acids are likely to be found (a) lining the channel through which K^+ passes, (b) in contact with the hydrophobic core of the phospholipid bilayer containing fatty acyl groups, (c) in the cytosolic domain of the protein, and (d) in the extracellular domain of the protein?
3. V-M-Y-F-E-N: This is the single-letter amino acid abbreviation for a peptide. What is the net charge of this peptide at pH 7.0? An enzyme called a *protein tyrosine kinase* can attach a phosphate to the hydroxyl group of a tyrosine (Y). What is the net charge of the peptide at pH 7.0 after it has been phosphorylated by a tyrosine kinase? What is the likely source of phosphate used by the kinase for this reaction?

4. Disulfide bonds help to stabilize the three-dimensional structure of proteins. What amino acids are involved in the formation of disulfide bonds? Does the formation of a disulfide bond increase or decrease entropy (ΔS)?
5. In the 1960s, the drug *thalidomide* was prescribed to pregnant women to treat morning sickness. However, thalidomide caused severe limb defects in the children of some women who took the drug, and its use for morning sickness was discontinued. It is now known that thalidomide was administered as a mixture of two stereoisomeric compounds, one of which relieved morning sickness and the other of which was responsible for the birth defects. What are stereoisomers? Why might two such closely related compounds have such different physiological effects?
6. Name the compound shown below.

Is this nucleotide a component of DNA, RNA, or both? Name one other function of this compound.

7. The chemical basis of blood-group specificity resides in the carbohydrates displayed on the surfaces of red blood cells. Carbohydrates have the potential for great structural diversity. Indeed, the structural complexity of the oligosaccharides that can be formed from four sugars is greater than that of the oligopeptides that can be formed from four amino acids. What properties of carbohydrates make this great structural diversity possible?
8. Calculate the pH of 1 L of pure water at equilibrium. How will the pH change after 0.008 moles of the strong base sodium hydroxide (NaOH) are dissolved in the water? Now, calculate the pH of a 50 mM aqueous solution of the weak acid 3-(*N*-morpholino) propane-1-sulfonic acid (MOPS) in

which 61 percent of the solute is in its weak acid form and 39 percent is in the form of MOPS's corresponding base (the pK_a for MOPS is 7.20). What is the final pH after 0.008 moles of NaOH are added to 1 L of this MOPS buffer?

9. Ammonia (NH_3) is a weak base that under acidic conditions becomes protonated to the ammonium ion in the following reaction:

$$NH_3 + H^+ \rightarrow NH_4{}^+$$

NH_3 freely permeates biological membranes, including those of lysosomes. The lysosome is a subcellular organelle with a pH of about 4.5–5.0; the pH of cytoplasm is about 7.0. What is the effect on the pH of the fluid content of lysosomes when cells are exposed to ammonia? *Note:* Ammonium ($NH_4{}^+$) does not diffuse freely across membranes.

10. Consider the binding reaction $L + R \rightarrow LR$, where L is a ligand and R is its receptor. When 1×10^{-3} M of L is added to a solution containing 5×10^{-2} M of R, 90 percent of the L binds to form LR. What is the K_{eq} of this reaction? How will the K_{eq} be affected by the addition of a protein that facilitates (catalyzes) this binding reaction? What is the dissociation equilibrium constant K_d?
11. What is the ionization state of phosphoric acid in the cytoplasm? Why is phosphoric acid such a physiologically important compound?

12. The $\Delta G^{\circ\prime}$ for the reaction $\mathrm{X} + \mathrm{Y} \rightarrow \mathrm{XY}$ is -1000 cal/mol. What is the ΔG at 25 $^{\circ}$C (298 $^{\circ}$Kelvin) starting with 0.01 M each of X, Y, and XY? Suggest two ways one could make this reaction energetically favorable.
13. According to health experts, saturated fatty acids, which come from animal fats, are a major factor contributing to coronary heart disease. What distinguishes a saturated fatty acid from an unsaturated fatty acid, and to what does the term *saturated* refer? Recently, trans unsaturated fatty acids, or trans fats, which raise total cholesterol levels in the body, have also been implicated in heart disease. How does the cis stereoisomer differ from the trans configuration, and what effect does the cis configuration have on the structure of the fatty acid chain?
14. Chemical modifications of amino acids contribute to the diversity and function of proteins. For instance, γ-carboxylation of specific amino acids is required to make some proteins biologically active. What particular amino acid undergoes this modification, and what is its biological relevance? Warfarin, a derivative of coumarin, which is present in many plants, inhibits γ-carboxylation of this amino acid and was used in the past as a rat poison. At present, it is also used clinically in humans. What patients might be prescribed warfarin and why?

CHAPTER 3

Protein Structure and Function

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

Computationally designed, hypothetical four-stranded fiber protein viewed down the fiber axis. Using advanced methods for protein design, the amino acid sequence of the staphylococcal nuclease protein was modified so that the individual, folded protein chains (shown in different colors) would stack into long strands. The design predicts that four long strands would assemble into a four-stranded fiber held together by the binding of hydrophobic helices located in the center of the fiber.

OUTLINE

3.1 Hierarchical Structure of Proteins
3.2 Protein Folding
3.3 Protein Binding and Enzyme Catalysis
3.4 Regulating Protein Function
3.5 Purifying, Detecting, and Characterizing Proteins
3.6 Proteomics

Proteins, which are polymers of amino acids called *polypeptides*, fold into three-dimensional structures of many sizes and shapes. Their three-dimensional diversity principally reflects variations in their amino acid sequences and in the lengths of the polypeptides. In general, a polypeptide will fold into only one or a few closely related three-dimensional shapes — called **conformations**. A key concept in understanding how a protein works is that *its function is often derived from its three-dimensional structure, and its three-dimensional structure is determined by its amino acid sequence and the noncovalent interactions that stabilize its structure*.

In many cases, the conformation, and thus the function, of a protein can change when that protein associates noncovalently or covalently with other molecules or ions. Through these associations, the function — also called the *activity* — of a protein can be *regulated* (e.g., turned "on" or "off," or "up" or "down") to permit cells to adapt to changing conditions. Altered conditions include changes in nutrient availability (Chapter 21), hormonal signaling (Chapters 15 and 16), communication with other cells (Chapters 20 and 23), the

developmental state of the organism, and the presence of pathogens (Chapter 24), along with many other factors.

How many proteins are there in a typical eukaryotic cell? We can calculate that there are about 7.9×10^9 protein molecules in a mammalian hepatocyte (a liver cell). (This calculation is worked out in Section 3.1.) It is estimated that a hepatocyte contains about 10,000 different proteins; thus each cell, *on average*, contains close to a million molecules of each type of protein. In reality though, the abundances of different proteins vary widely, from the quite rare insulin-binding receptor protein (2×10^4 molecules per cell) to the structural protein actin (5×10^8 molecules per cell). Every cell closely regulates the abundance of each of its proteins so that they are present in the appropriate quantities to support the cell's needs at any given time. We will learn more about the mechanisms used by cells to regulate protein levels later in this chapter and in Chapters 8 and 9.

Because of their many different shapes and chemical properties, proteins can perform a dazzling array of functions inside and outside cells that either are essential for life or provide a selective evolutionary advantage to the cell or organism that contains them. It is, therefore, not surprising that characterizing the structures and activities of proteins — and how these change in response to regulation — is a fundamental prerequisite for understanding how cells work. Much of this textbook is devoted to examining how

proteins act with one another or with other types of molecules (e.g., DNA) to allow cells to live and function properly. In this chapter we emphasize the basic principles underlying the structures and functions of proteins and the regulation of their activity. We also look at some of the many methods used to study them.

Although their structures are diverse, most proteins can be grouped into a few broad functional classes. *Structural proteins*, for example, determine the shapes of cells and their extracellular environments and serve as guide wires or rails to direct the intracellular movement of molecules and organelles. Structural proteins are usually formed by the assembly of multiple protein subunits into very large and often very long structures. *Scaffold proteins* bring other proteins together into ordered arrays to perform specific functions more efficiently than those proteins would if they were not assembled together. *Enzymes* are proteins that catalyze chemical reactions (sometimes called *molecular transformations*). These molecular transformations are the fundamental activities in metabolic pathways (Chapter 12). They can also result in the modification of proteins to alter their activities (e.g., phosphorylation and dephosphorylation to activate and inactivate other proteins). *Membrane transport proteins* are embedded in cellular membranes and permit the flow of ions and molecules across the membranes. *Regulatory proteins* act as signals, sensors, and switches to control activities of cells by altering the functions of other proteins and genes. Regulatory proteins include *signaling*

proteins, such as some hormones and cell-surface receptors that transmit extracellular signals to the cell interior. *Motor proteins* are responsible for the *movement* of other proteins, organelles, and cells — even whole organisms. There are additional proteins that don't fit neatly into one of these classes. For example, fish that live in frigid waters — the Antarctic notothenioids and Arctic cods — have antifreeze proteins in their circulatory systems to prevent water crystallization. Many proteins are members of more than one class, such as some cell-surface signaling receptors that are enzymes and regulatory proteins because they transmit signals from outside to inside cells by catalyzing chemical reactions. To accomplish their diverse missions efficiently, some proteins assemble into very large complexes, often called *molecular machines*.

How do proteins perform so many diverse functions? They do so by exploiting three simple mechanisms. The most fundamental is *binding*: proteins bind to one another, to other macromolecules such as DNA, and to small molecules and ions. Binding is based on molecular complementarity between a protein and its binding partner, as described in Chapter 2. A second mechanism is enzymatic *catalysis*. In enzymes, the proper conformation of the protein will place some amino acid side chains and some carboxyl and amino groups of its backbone into positions that permit the catalysis of covalent bond rearrangements in other molecules (called *substrates* of the enzyme). A third mechanism is *regulation* of protein activity. Typically, a protein's shape or activity is altered

through noncovalent (binding) or covalent (catalysis) association of molecules or ions with the protein. In many cases, this binding or catalysis induces a conformational change in the protein and that influences its activity.

A complete understanding of how proteins permit cells to live and thrive requires that we identify and characterize all of the proteins used by a cell. In a sense, molecular cell biologists want to compile a complete protein "parts list" and then construct a "user's manual" that describes how these proteins work. Compiling a comprehensive inventory of proteins has become feasible in recent years thanks to the sequenced genomes — complete sets of genes — of many organisms. From a computer analysis of a genome's sequence, researchers can deduce the amino acid sequences and approximate number of different types of proteins the genome encodes (see Chapter 6). It is also possible to determine the sequences and relative amounts of a substantial fraction of the messenger RNAs (mRNAs) in individual cells or most of the mRNAs (the transcriptome) from a collection of similar cells and thus deduce what subset of proteins encoded in the genome is made (*expressed*) in a given type of cell. DNA and mRNA sequencing are indirect methods of characterizing the potential collection of proteins in cells. There are also methods that directly measure the collection of proteins in samples of cells, which we discuss in Sections 3.5 and 3.6.

The term *proteome* was coined to refer to the entire protein complement of an organism, organ, or a particular type of cell within an organism. The human genome contains about 21,500 genes that encode proteins. However, variations in mRNA production, such as alternative splicing (see Chapter 9), and more than a hundred types of protein modifications may generate hundreds of thousands of distinct types of human proteins. By comparing the sequences and structures of proteins of unknown function with those of proteins of known function, scientists can often deduce much about what the unknown proteins do. In the past, a protein's function was characterized by genetic, biochemical, or physiological methods before the particular protein had been identified. In the modern genomic and proteomic era, a protein is often identified before its function is determined.

In this chapter, we begin our study of how the structure of a protein gives rise to its function, a theme that recurs throughout this book (Figure 3-1). In Section 3.1, we examine how linear chains of amino acids are arranged in a three-dimensional structural hierarchy. The next section discusses how proteins fold into these structures. We then turn to protein function, focusing on enzymes, those proteins that catalyze chemical reactions. Our focus on protein structure and function is part of a broader interest in cell biology in the principles relating biological structure and function. These principles were initially formulated by biologists Johann von Goethe (1749–1832), Ernst Haeckel (1834–1919), and D'Arcy Thompson (1860–1948),

whose work has been widely influential in biology and beyond. Indeed, their ideas greatly influenced the school of organic architecture pioneered in the early twentieth century that is epitomized by the dicta “form follows function” (Louis Sullivan) and “form is function” (Frank Lloyd Wright). After considering protein structure and function, we turn to various mechanisms that cells use to control the activities and life spans of proteins. Particularly important control mechanisms are allosteric effector-binding, covalent phosphorylation, and ubiquitinylation of proteins. The chapter concludes with a discussion of commonly used techniques for identifying, isolating, and characterizing proteins, and a discussion of the burgeoning field of proteomics.

FIGURE 3-1 Overview of protein structure and function. (a) Proteins have a hierarchical structure. A polypeptide's linear sequence of amino acids linked by peptide bonds (primary structure) folds into local helices or sheets (secondary structure) that pack into a complex three-dimensional shape (tertiary structure). Some individual polypeptides associate into multichain complexes

(quaternary structure), which in some cases can be very large, consisting of tens to hundreds of subunits (supramolecular complexes). (b) Proteins perform numerous functions, including organizing the genome, organelles, cytoplasm, protein complexes, and membranes in three-dimensional space (*structure*); monitoring the environment and transmitting information (*signaling*); moving small molecules and ions across membranes (*transport*); catalyzing chemical reactions that result in the *molecular transformation* of one molecule into another; and generating force for *movement* (via motor proteins). These functions and others arise from mechanisms involving *binding*, *catalysis*, and *regulation*.

3.1 Hierarchical Structure of Proteins

Here we consider the architecture of proteins at four levels of organization: primary, secondary, tertiary, and quaternary (Figure 3-2).

FIGURE 3-2 Four levels of protein hierarchy. (a) The linear sequence of amino acids linked together by peptide bonds is the primary structure. (b) Folding of the polypeptide chain into local α helices or β sheets represents secondary structure. (c) Secondary structural elements, together with various loops and turns in a single polypeptide chain, pack into a larger, independently stable tertiary structure, which may include distinct domains. (d) Some proteins consist of more than one polypeptide associated together in a quaternary structure.

The Primary Structure of a Protein Is Its Linear Arrangement of Amino Acids

As discussed in Chapter 2, proteins are polymers constructed out of 20 different types of amino acids. Individual amino acids are linked together in linear chains by covalent amide bonds, called **peptide bonds**, formed between the carboxyl group of one amino acid and the amino group of the adjacent amino acid (Figure 3-3a). An amino acid in a protein chain is sometimes referred to as a *residue*. The repeated amide N, α carbon (C_α), carbonyl C, and oxygen atoms of each amino acid residue form the *backbone* of a protein molecule from which the various side-chain groups project (Figure 3-3b, c). Thus one end of a protein has a free (unlinked) amino group (the *N-terminus*) and the other end has a free carboxyl group (the *C-terminus*). The **primary structure** of a protein is simply the linear covalent arrangement, or sequence, of the amino acid residues that compose it and is conventionally written with its N-terminal amino acid on the left and its C-terminal amino acid on the right. The amino acids are numbered sequentially starting from the N-terminus.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 3-3 Structure of a polypeptide. (a) Individual amino acids are linked together by peptide bonds, which form via reactions that result in a loss of

water. R_1, R_2, and so on, represent the side chains (R groups) of amino acids. (b) Linear polymers of amino acids linked by peptide bonds are called *polypeptides*, which have a free (unlinked) amino end (N-terminus) and a free carboxyl end (C-terminus). (c) A ball-and-stick model shows peptide bonds (yellow) linking the amino nitrogen atom (blue) of one amino acid (aa) with the carbonyl carbon atom (gray) of an adjacent one in the chain. The R groups (green) extend from the α-carbon atoms (black) of the amino acids. These side chains largely determine the distinct properties of individual proteins.

The first primary structure of a protein determined was that of insulin in the early 1950s. Today the number of known protein sequences exceeds 10 million and is growing daily. Many terms are used to denote the chains formed by the polymerization of amino acids. A short chain of amino acids linked by peptide bonds and having a defined sequence is called an **oligopeptide**, or simply a **peptide**; longer chains are referred to as **polypeptides**. Peptides generally contain fewer than 20–30 amino acid residues, whereas polypeptides are often 200–500 residues long and can be longer. The longest protein described to date is the muscle protein titin, some forms of which are more than 34,000 residues long. We generally reserve the term **protein** for a polypeptide (or complex of polypeptides) that has a well-defined three-dimensional structure, although there are exceptions described later in this chapter.

The size of a protein or a polypeptide is expressed either as its mass in **daltons** (a dalton is 1 atomic mass unit) or as its molecular weight (MW), which is a dimensionless number equal to the mass in daltons. For example, a 10,000-MW protein has a mass of 10,000

daltons (Da), or 10 kilodaltons (kDa). In Section 3.5, we will consider different methods for measuring the sizes and other physical characteristics of proteins. The precise molecular weight of a protein that has not been covalently modified is readily determined by summing up the weights of all of its constituent amino acids as determined from its amino acid sequence. The proteins encoded by the yeast genome, for example, have an average molecular weight of 52,728 and contain, on average, 466–amino acid residues. The average molecular weight of amino acids in proteins is 113, taking into account their average relative abundances. This value can be used to estimate the number of residues in a protein of unknown sequence if you know its molecular weight or, conversely, to estimate from the number of residues in a protein its likely molecular weight. Covalent modification of one or more amino acids in a protein — for example, by phosphorylation or glycosylation (see Chapters 2 and 13) — alters the mass of those residues and thus the mass of the protein in which they reside.

In the introduction we noted that a eukaryotic cell, on average, contains close to 7.9×10^9 molecules of protein. How do we estimate this? Let's do a simple calculation for a hepatocyte (a major type of cell in the mammalian liver). A hepatocyte, roughly a cube 15 μm (0.0015 cm) on a side, has a volume of 3.4×10^{-9} cm^3 (or milliliters, ml). Assuming a cell density of 1.03 g/ml, the cell would weigh 3.5×10^{-9} g. Since protein accounts for approximately 20 percent of a cell's weight, the total weight of cellular protein is 7×10^{-10} g.

Assuming that an average protein has a molecular weight of about 53,000 g/mol, we can calculate the total number of protein molecules per hepatocyte as about 7.9×10^9 from the total protein weight and Avogadro's number, the number of molecules per mole of any chemical compound (6.02×10^{23}).

Secondary Structures Are the Core Elements of Protein Architecture

The second level in the hierarchy of protein structure is **secondary structure**. Secondary structures are stable spatial arrangements of segments of a polypeptide chain held together by hydrogen bonds between backbone amide and carbonyl groups and often involving repeating structural patterns. The propensity of a segment of a polypeptide chain to form any given secondary structure depends on its amino acid sequence (see Section 3.2). A single polypeptide may contain multiple types of secondary structure in various portions of the chain, depending on its sequence. The principal secondary structures are the **alpha (α) helix**, the **beta (β) sheet**, and the short, U-shaped **beta (β) turn**. Parts of a polypeptide that don't form these secondary structures may nevertheless have a well-defined, stable shape and are said to have an *irregular* structure. The term *random coil* applies to highly flexible parts of a polypeptide chain that have no stable, fixed three-dimensional structure. Random coils are said to be *disordered*. In an average protein, 60

percent of the polypeptide chain exists as α helices and β sheets; the remainder of the molecule is in irregular structures, coils, and turns or is disordered. Thus α helices and β sheets are the major internal supportive elements in most proteins. Here we explore the shapes of secondary structures and the forces that favor their formation. In later sections, we examine how arrays of secondary structure fold together into larger, more complex arrangements called *tertiary structure*.

The α Helix

In a polypeptide segment folded into an α helix, the backbone forms a spiral structure in which the carbonyl oxygen atom of each peptide bond is hydrogen-bonded to the amide hydrogen atom of the amino acid four residues farther along the chain in the direction of the C-terminus (Figure 3-4). Within an α helix, all the backbone amino and carboxyl groups are hydrogen-bonded to one another (conferring substantial stability) except at the very beginning and end of the helix.

FIGURE 3-4 The α helix, a common secondary structure in proteins. The polypeptide backbone (highlighted as a ribbon) is folded into a spiral that is held in place by hydrogen bonds between backbone oxygen and hydrogen atoms linked to nitrogen. Only hydrogens involved in bonding are shown. The outer surface of the helix is covered by the side-chain R groups (green). There is a complete turn of the spiral every 3.6 residues. An α helix 36 amino acids long has 10 turns of the helix and is 5.4 nm long (0.54 nm per turn).

The stable arrangement of hydrogen-bonded amino acids in the α helix holds the backbone in a straight, rodlike cylinder from which the side chains point outward. The characteristics of the side chains entirely determine the relative hydrophobic or hydrophilic quality of a particular helix within a protein. In water-soluble proteins, hydrophilic helices with polar side chains extending outward tend to be found on the outside surfaces, where they can interact with the aqueous environment, whereas hydrophobic helices with nonpolar, hydrophobic side chains tend to be buried within the core of the folded protein. Proteins embedded in the hydrophobic core of cellular membranes (see Chapter 10) often use one or more hydrophobic helices that are 20–25 residues long to cross the membrane. The amino acid proline is usually not found in α helices because the covalent bonding of its amino group with a carbon in the side chain (see Figure 2-14) prevents its participation in stabilizing the backbone through normal hydrogen bonding. While the classic α helix is the most intrinsically stable and most common helical form in proteins, there are variations, such as more tightly or loosely twisted helices. For example, in a specialized helix called a *coiled coil* (described several sections farther on), the helix is more tightly wound (3.5 residues and 0.51 nm per turn).

The β Sheet

The β sheet consists of laterally packed *β strands*. Each β strand is a short (5–8-residue), nearly fully extended polypeptide segment.

Hydrogen bonds form between the carbonyl oxygen atom of each residue in one β strand and the amide hydrogen atom of a residue in a separate, but adjacent, β strand. These hydrogen bonds are oriented perpendicularly to the chains of backbone atoms (Figure 3-5a). These distinct β strands (indicated as green and blue arrows in the figure) may be located either within a single polypeptide chain, with short or long loops between the β strand segments, or on different polypeptide chains in a protein composed of multiple polypeptides.

FIGURE 3-5 The β sheet, another common secondary structure in proteins. (a) Top view of a three-stranded β sheet. Each strand is highlighted by a ribbonlike

arrow with alternating blue and green segments that is pointed with an N-to-C orientation, with the loops of connecting residues indicated by thick black lines. In this antiparallel β sheet, each strand (arrow) points in the direction opposite to that of the adjacent strand. The stabilizing hydrogen bonds between the β strands are indicated by green dashed lines. (b) Side view of an antiparallel β sheet. The projection of the R groups (green) above and below the plane of the sheet is obvious in this view. The fixed bond angles in the polypeptide backbone produce a pleated contour represented in panel (a) by the alternating colored segments. (c) Top view of two β sheets, in which N-to-C orientations are represented by arrows. The individual strands are either antiparallel, in which the strands alternately point in opposite directions (*left*), or parallel, in which all strands point in the same direction (*right*).

Figure 3-5b shows how two or more β strands align into adjacent rows, forming a nearly two-dimensional β pleated sheet (or simply *pleated sheet*). Hydrogen bonds within the plane of the sheet hold the β strands together as the side chains stick out above and below the plane. Adjacent β strands can be oriented (N-terminus to C-terminus) in alternating opposite (antiparallel) directions (see Figures 3-5a and 3-5c, *left*) or in the same (parallel) direction (Figure 3-5c *right*). In some proteins, the β sheets curve around and form a cylinder, called a *β barrel*. When these proteins are embedded in membranes, the cylindrical beta sheet can form a hydrophilic central pore through which ions and small molecules may flow (see Chapter 10).

The β Turn

Composed of four residues, β turns form sharp, U-shaped bends located on the surface of a protein. Beta turns reverse the direction of the polypeptide backbone and are often stabilized by a hydrogen bond between their end residues (Figure 3-6). They help long polypeptides fold into highly compact structures. The direction of the polypeptide backbone may also be reversed by longer segments of the polypeptide that form bends or loops with varying conformations.

FIGURE 3-6 Structure of a β turn. Composed of four residues, β turns reverse the direction of a polypeptide chain (resulting in a 180° U-turn). Glycine and proline are commonly found in β turns. The lack of a large side chain in glycine and the presence of a built-in bend in proline allow the polypeptide backbone to fold into a tight U shape. The C_α carbons of the first and fourth residues are usually less than 0.7 nm apart, and those residues are often linked by a hydrogen bond. β turns facilitate the folding of long polypeptides into compact structures.

In many cases, the secondary structure of a polypeptide segment is determined primarily by its sequence, although in some cases long-range interactions between different parts of a polypeptide can influence the propensity of those parts to form a given secondary structure. The relationships of amino acid sequence and secondary structure have been analyzed in large numbers of known protein structures ($\sim$50,000). Investigators can use these relationships to predict the secondary structures embedded within the sequence of a polypeptide chain whose structure has not been determined ($\sim$250 million sequences are known, $\sim$86 billion amino acids!). Investigators have used a variety of sophisticated methods to predict secondary structure, including methods that consider evolutionary relationships or apply artificial intelligence (including deep learning based on artificial neural networks). These predictions are not perfect, but they are very good. When predictions of secondary structure are tested against experimentally determined structures, their accuracy can be as high as 84 percent. It is noteworthy that predictions of α helices are better than those for β sheets, which are more accurate than those for coils or loops. Such predictions can be used to predict the consequences of a mutation in a gene on the encoded protein's secondary structures, and possibly on its function.

Structural Motifs Are Regular Combinations of Secondary Structures

A particular combination of two or more secondary structures that forms a distinct three-dimensional structure, which appears in multiple proteins, is called a **structural motif**. A structural motif — an alternative name is *supersecondary structure* — is often associated with a specific function, such as binding to a particular ion or small molecule, such as calcium or ATP. Some structural motifs are stable after being isolated from the rest of a protein and are thus called *structural domains*, as we shall see shortly. However, other structural motifs do not form thermodynamically stable structures in the absence of other portions of the protein and are thus not considered independent structural domains.

One common structural motif is the α helix–based *coiled coil*. In this motif, α helices from two, three, or even four separate polypeptide chains coil about one another — resulting in a coil of coils; hence the name (Figure 3-7a). Many proteins, including fibrous proteins and DNA-regulating proteins called *transcription factors* (see Chapter 8) assemble into dimers or trimers by using a coiled-coil motif. The individual helices bind tightly to one another because each helix has a strip of aliphatic (hydrophobic, but not aromatic) side chains (leucine, valine, etc.) running along one side of the helix that interacts with a similar strip in the adjacent helix, thus sequestering the hydrophobic groups away from water and stabilizing the assembly of multiple independent helices. These hydrophobic strips are generated along only one side of the helix because the primary structure of each helix is composed of repeating seven–amino acid

units, called *heptads* or *heptad repeats*, in which the side chains of the first and fourth residues are aliphatic and the other side chains are often hydrophilic (see Figure 3-7a). Because hydrophilic side chains extend from one side of the helix and hydrophobic side chains extend from the opposite side, the overall helical structure is amphipathic. Because leucine frequently appears in the fourth positions and the hydrophobic side chains merge together like the teeth of a zipper, these structural motifs are also called **leucine zippers**.

A heptad repeat is an example of a *sequence motif*, a pattern of amino acids in a contiguous segment of a protein that can be found in many proteins, and sometimes in many copies within one protein. The sequence motif may be either an exact copy of the same sequence in every protein or a pattern of similar residues that do not have precisely the same sequence, such as the common spacing of aliphatic residues in a heptad repeat.

Many different structural motifs contain α helices. A common calcium-binding motif called the **EF hand** contains two short α helices connected by a loop (Figure 3-7b). This structural motif, one of several **helix-turn-helix** and **helix-loop-helix** structural motifs, is found in more than a hundred proteins and is used for sensing calcium levels. Ca^{2+} ion binds to oxygen atoms in conserved residues in the loop when the concentration of Ca^{2+} in the cell is high enough. Sometimes the binding induces a conformational

change in the protein bearing the EF hand, altering the protein's activity. Thus calcium concentrations can directly control the structures and functions of certain proteins. Somewhat different helix-turn-helix and **basic helix-loop-helix (bHLH)** structural motifs are used for protein binding to DNA and, consequently, for the regulation of gene activity (see Chapter 8). Yet another structural motif commonly found in proteins that bind RNA or DNA is the **zinc finger**. This motif contains three secondary structures — an α helix and two β strands with an antiparallel orientation — that form a fingerlike bundle held together by a zinc ion (Figure 3-7c).

FIGURE 3-7 Motifs of protein secondary structure. (a) This parallel, two-stranded coiled-coil motif (*left*) is characterized by two α helices wound around each other. The backbone of the residues is represented as a ribbon, as illustrated in Figure 3-4, with atoms of only some of the side chains represented as balls. Helix packing is stabilized by interactions between hydrophobic side chains (red and blue) present at regular intervals along each strand and found along the seam of the intertwined helices. Each α helix exhibits a characteristic heptad repeat sequence with a hydrophobic residue often, but not always, at positions 1

and 4, as indicated. The coiled-coil nature of this structural motif is more apparent in long coiled coils containing many such sequence motifs (*right*). (b) An EF hand, a type of helix-loop-helix motif, consists of two helices connected by a short loop in a specific conformation. The backbone of the residues is represented as a ribbon with only some of the side chains represented as balls (atoms) and sticks (bonds). This structural motif is common to many proteins, including many calcium-binding and DNA-binding regulatory proteins. In calcium-binding proteins such as calmodulin, oxygen atoms from five residues in the acidic glutamate- and aspartate-rich loop and one water molecule form ionic bonds with a large Ca^{2+} ion (green). (c) The zinc-finger motif is present in many DNA-binding proteins that help regulate transcription. A Zn^{2+} ion is held between a pair of β strands (blue) and a single α helix (red) by a pair of cysteine residues and a pair of histidine residues. The two invariant cysteine residues are usually at positions 3 and 6, and the two invariant histidine residues are at positions 20 and 24 in this 25-residue motif.

The relationship between the primary structure of a polypeptide chain and the structural motif into which a portion of it folds is not always straightforward. The amino acid sequences responsible for any given structural motif in different proteins may be very similar to one another. In other words, a common *sequence motif* can result in a common structural motif. This is the case for the heptad repeats that form coiled coils. However, it is also possible for seemingly unrelated amino acid sequences to fold into a common structural motif, so it is not always possible to predict which amino acid sequences will fold into a given structural motif. Conversely, it is possible that a commonly occurring sequence motif will not fold into a well-defined structural motif. Sometimes short sequence

motifs that have an unusual abundance of a particular amino acid, such as proline or aspartate or glutamate, are called *domains*; however, these and other short contiguous segments are more appropriately called *sequence motifs* than domains, as the latter term has a distinct meaning that we will define shortly.

We will encounter numerous additional motifs in our discussions of proteins in this and other chapters. The presence of the same structural motif in different proteins with similar functions clearly indicates that these useful combinations of secondary structures have been conserved in evolution.

Tertiary Structure Is the Overall Folding of a Polypeptide Chain

Tertiary structure refers to the overall conformation of a polypeptide chain — that is, the three-dimensional arrangement of all its amino acid residues. In contrast to secondary structures, which are stabilized only by hydrogen bonds, tertiary structure is stabilized primarily by hydrophobic interactions between nonpolar side chains, together with van der Waals interactions and hydrogen bonds involving both polar side chains and backbone amino and carboxyl groups. These stabilizing forces hold together elements of secondary structure — α helices, β strands, turns, and loops — and structural motifs. Because the interactions stabilizing tertiary

structures are often weaker than those stabilizing secondary structure, the tertiary structure of a protein is not necessarily rigidly fixed, but can undergo continual minute fluctuations. Some segments within the tertiary structure of a protein can be so mobile that they are considered to be disordered — that is, lacking a single, well-defined, stable, three-dimensional structure. This variation in structure has important consequences for the function and regulation of proteins.

The chemical properties of amino acid side chains help define tertiary structure. In some proteins — for example, those that are secreted from cells or are cell-surface proteins that face the extracellular environment — *disulfide bonds* form between the side chains of cysteine residues. Disulfide bonds can covalently link regions of the proteins, thus restricting the proteins' flexibility and increasing the stability of their tertiary structures. Amino acids with charged hydrophilic polar side chains tend to be on the outer surfaces of water-soluble proteins; by interacting with water, they increase the protein's solubility in water. Moreover, these polar side chains can form noncovalent interactions with other water-soluble molecules, including other proteins. In contrast, amino acids with hydrophobic nonpolar side chains are usually sequestered away from the water-facing surfaces of a protein, in many cases forming a water-insoluble central core. This observation led to what's known as the *oil drop model* of protein conformation because the core of a protein is relatively hydrophobic, or *oily* (Figure 3-8). Hydrophilic

polar side chains that are uncharged are found both on the surface and in the inner core of water-soluble proteins.

FIGURE 3-8 The oil drop model of protein folding. The hydrophobic and hydrophilic residues of a polypeptide chain can be distributed throughout its linear sequence as illustrated in the unfolded protein (*top*). The color scale denotes the most hydrophilic residues (blue) to the most hydrophobic (yellow). When the protein folds (*bottom left*), hydrophilic (charged and uncharged polar) side chains will often be exposed on the protein's surface, where they can form stabilizing interactions with surrounding water and ions. In contrast, the hydrophobic residues tend to cluster together in the inner core, somewhat like drops of oil in an aqueous liquid, driven away from the aqueous surroundings

by the hydrophobic effect (see Chapter 2). These core residues are more easily seen when several surface residues are removed (*bottom right*).

[Data from M. C. Vaney et al., 1996, *Acta Crystallogr., Sect. D*. **52**:505, PDB ID 193l.]

As you might expect, our ability to predict the tertiary structure for most proteins from primary sequence is not as advanced as our ability to predict secondary structure from sequence. One method to assess the quality of a tertiary structure prediction is to use the total score of the global distance test (a scale from 0 to 100), which compares the prediction with an experimentally determined structure. A score of <20 is a clearly incorrect prediction, scores of 80–90 are close to identifying the positions of individual atoms, and 100 is perfect. Current methods result in predictions around 57, which provide a good representation of the overall chain folding, but often have serious errors when compared to experimental results. At this time, predictions are better for shorter (length <150 residues) polypeptides.

Different Ways of Depicting the Conformation of Proteins Convey Different Types of Information

The simplest way to represent three-dimensional protein structure is to trace the course of the backbone atoms, sometimes only the C_α

atoms, with a solid line — or narrow tube — called a C_α *backbone trace* (Figure 3-9a); the most complex representation, called a *ball-and-stick model*, shows every atom (Figure 3-9b). The C_α backbone trace shows the overall folding of the polypeptide chain without consideration of the amino acid side chains; the ball-and-stick model (with balls representing atoms and sticks representing bonds) details the interactions between side-chain atoms, including those that stabilize the protein's conformation and interact with other molecules, as well as the atoms of the backbone. Even though both views are useful, the elements of secondary structure are not always easily discerned in them. Another type of representation, called a *ribbon diagram*, uses common shorthand symbols for depicting secondary structure — for example, coiled ribbons or solid cylinders for α helices, flat ribbons or arrows for β strands, and flexible thin strands for β turns, coils, and loops (Figure 3-9c). In a variation of the basic ribbon diagram, ball-and-stick or space-filling models of side chains are attached to the backbone ribbon, as we have seen in Figure 3-7. In this way, side chains of interest can be visualized clearly in the context of the secondary structure that is represented by the ribbons.

FIGURE 3-9 Five ways to visualize the protein Ras with its bound GDP. (a) The C_α backbone trace demonstrates how the polypeptide is tightly packed into a small volume. (b) A ball-and-stick representation reveals the locations of all atoms. (c) Turns and loops connect pairs of helices and strands. (d) A water-accessible surface reveals the numerous lumps, bumps, and crevices on the protein surface. Regions of positive charge are shaded blue, and regions of negative charge are shaded red. (e) Hybrid model combines ribbon and transparent surface models.

[Data from E. F. Pai et al., 1990, *EMBO J.* **9**:2351–2359, PDB ID 5p21.]

However, none of these three ways of representing protein structure conveys much information about the atoms that are on the protein's surface and in contact with the protein's environment. The surface is of interest because it is where other molecules usually bind to a protein. Thus a useful alternative way to represent proteins is to show only the surface and use colors to highlight regions having a

common chemical character, such as hydrophobicity or hydrophilicity, and charge characteristics, such as positive (basic) or negative (acidic) side chains (Figure 3-9d). Such models reveal the topography of the protein surface and the distribution of charge, both important features of binding sites, as well as clefts in the surface where other molecules may bind. This view represents a protein as it is "seen" by other molecules. Hybrid models (Figure 3-9e) combine features of multiple types of protein representation.

Domains Are Modules of Tertiary Structure

Distinct regions of protein structure are often referred to as **domains**. There are three main classes of protein domains: functional, structural, and topological. A *functional domain* is a region of a protein that exhibits a particular activity characteristic of that protein, usually even when isolated from the rest of the protein. For instance, a particular region of a protein may be responsible for a catalytic activity (e.g., a kinase domain that covalently adds a phosphate group to another molecule) or its binding ability (e.g., a DNA-binding domain or a membrane-binding domain). Functional domains are often identified experimentally by whittling down a protein to its smallest active fragment with the aid of **proteases**, enzymes that cleave one or more peptide bonds in a target polypeptide. Alternatively, the DNA encoding a protein can be

modified so that when the modified DNA is used to generate a protein, only a particular region, or domain, of the full-length protein is made. Thus it is possible to determine if specific parts of a protein are responsible for particular activities exhibited by the protein. Indeed, functional domains are often also associated with corresponding structural domains.

A *structural domain* is a region about 40 or more amino acids in length, arranged in a single, stable, and distinct structure often comprising one or more secondary structures or structural motifs. Many structural domains can fold into their characteristic structures independently of the rest of the protein in which they are embedded. As a consequence, distinct structural domains can be linked together — sometimes by stretches of polypeptide chain called *spacers* — to form a large multidomain protein (somewhat like beads on a string). Each of the polypeptide chains in the trimeric flu virus hemagglutinin, for example, contains a globular domain and a fibrous domain (Figure 3-10a).

FIGURE 3-10 Tertiary and quaternary levels of structure. The protein pictured here, hemagglutinin (HA), is found on the surface of the influenza virus. This long molecule has three identical subunits, each composed of two polypeptide chains, HA_1 and HA_2. (a) The tertiary structure of each HA subunit comprises the folding of its helices and strands into a compact structure that is 13.5 nm long and divided into two domains. The membrane-distal domain (silver) is folded into a globular conformation. The membrane-proximal domain (gold) has a fibrous, stemlike conformation owing to the alignment of two long α helices (cylinders) of HA_2 with β strands in HA_1. Short turns and longer loops, many of them at the surface of the molecule, connect the helices and strands in each chain. (b) The quaternary structure of HA is stabilized by lateral interactions between the long helices (cylinders) in the fibrous domains of the three subunits (gold, blue, and green), forming a triple-stranded coiled-coil

stalk. Each of the distal globular domains in HA binds sialic acid (red) on the surface of target cells. Like many membrane proteins, HA contains several covalently linked carbohydrate chains (not shown).

[Data from S. J. Gamblin et al., 2004, *Science* **303**:1838–1842, PDB ID 1ruz.]

Structural domains frequently are also functional domains in that they can have an activity independent of the rest of the protein. Structural domains can be incorporated as modules into different proteins. The modular approach to protein architecture is particularly easy to recognize in large proteins, which tend to be mosaics of different domains that confer distinct activities and thus can perform different functions simultaneously. As many as 80 percent of the proteins in eukaryotes have multiple structural domains. The organization (order) of domains within a multidomain protein is called the *domain architecture*. A useful simile is that a protein is like a sentence. The amino acid residues are like letters, spaces, and punctuation marks, and the structural domains are like words, each having its distinct activity, and, when joined together into a *sentence*, they generate a protein with a distinctive function.

Thousands of structural domains have been identified in proteins. Some of these are not very common, whereas others are found in many different proteins. Indeed, by some estimates, only nine major types of structural domains account for as much as a third of all the structural domains in all proteins. Structural domains can be recognized in proteins whose structures have been determined by x-ray crystallography or nuclear magnetic resonance (NMR) analysis

or in images captured by electron microscopy (see Section 3.5). For example, the epidermal growth factor (EGF) domain is a structural domain that is present in several proteins (Figure 3-11). EGF is a small, soluble peptide hormone that binds to cells in the embryo and in skin and connective tissue in adults, causing them to divide. It is generated by proteolytic cleavage (breaking of a peptide bond) between repeated EGF domains in the EGF precursor protein, which is anchored in the plasma membrane by a membrane-spanning domain. EGF domains with sequences similar to, but not identical to, that of the EGF peptide hormone are present in other proteins and can be liberated by proteolysis. These proteins include tissue plasminogen activator (TPA), a protease that is used to dissolve blood clots in heart attack victims; Neu protein, which takes part in embryonic differentiation; and Notch protein, a receptor protein in the plasma membrane that functions in signaling and is important for development (see Chapter 16). Besides the EGF domain, these three proteins have other domains in common with other proteins. For example, TPA possesses a trypsin domain, a functional domain found in some proteases.

FIGURE 3-11 Modular nature of protein domains. Epidermal growth factor (EGF) is generated by proteolytic cleavage of a precursor protein containing multiple EGF domains (green) and a membrane-spanning domain (blue). An EGF domain is also present in the Neu protein and in tissue plasminogen activator (TPA). These proteins also contain other widely distributed domains, indicated by shape and color. See I. D. Campbell and P. Bork, 1993, *Curr. Opin. Struc. Biol.* **3**:385.

Regions of proteins that are defined by their distinctive spatial relationships to the rest of the protein are *topological domains*. For example, some proteins associated with cell-surface membranes have a part extending inward into the cytoplasm (cytoplasmic domain), a part embedded within the phospholipid bilayer (membrane-spanning domain), and a part extending outward into the extracellular space (extracellular domain). Each of these topological domains can comprise one or more structural and functional domains. It is also common for the region of a protein at the N-terminus or C-terminus to be called the *N-terminal* or *C-terminal domain*, respectively.

In Chapter 7, we will consider the mechanism by which the gene segments that correspond to domains became shuffled in the course of evolution, resulting in their appearance in many proteins. Once a functional, structural, or topological domain has been identified and characterized in one protein, it is possible to use that information to search for similar domains in other proteins and to suggest potentially similar functions for those domains in those proteins.

Comparing Protein Sequences and Structures Provides Insight into Protein Function and Evolution

Analyses of many diverse proteins have conclusively established a relation between the amino acid sequence, three-dimensional structure, and function of proteins. A good rule of thumb is that the greater the similarity of the sequences of two polypeptide chains, the more likely they are to have similar three-dimensional structures and similar functions. Although this comparative approach is very powerful, caution must always be exercised when attributing to one protein, or a part of a protein, a function or structure similar to that of another protein based only on amino acid sequence similarities. There are examples in which proteins with similar overall structures display different functions, as well as cases in which proteins unrelated in amino acid sequence or function nevertheless have very similar folded tertiary structures. In

many cases, however, such sequence comparisons provide important insights into protein structure and function.

Investigators have increased the use of protein sequence comparisons to study protein structure and function as the genomes and transcriptomes of more and more organisms are sequenced, because a vast array of protein sequences ($\sim$250 million) has been deduced from the nucleic acid sequences. Indeed, the molecular revolution in biology during the last decades of the twentieth century created a new scheme of biological classification based on similarities and differences in the amino acid sequences of proteins. Proteins that have a common ancestor are referred to as **homologs**. The main evidence for **homology** among proteins, and hence for their common ancestry, is similarity in their sequences, which is often reflected in similar structures. We can describe homologous proteins as belonging to a *family* and can trace their lineage — how closely or distantly they are related to one another in an evolutionary sense — from comparisons of their sequences. Generally more closely related proteins exhibit greater sequence similarity than more distantly related proteins because, over evolutionary time, alterations in the DNA sequences accumulate in the genes encoding these proteins. The folded three-dimensional structures of homologous proteins may be similar even if some parts of their primary structure show little evidence of sequence homology.

Based on their sequences, structural similarities, evolutionary histories and functions, related proteins have been classified as belonging to hierarchical sets of proteins called *superfamilies, groups, subgroups, families*, and *subfamilies*. The sequences of members of each subfamily are more similar to each other than they are to those of members of other subfamilies within the same family. Initially, proteins with relatively high sequence similarities (>50 percent exact amino acid matches, or *identities*) and related functions or structures were defined as an evolutionarily related family, while a superfamily encompassed two or more families in which the interfamily sequences matched less well (∼30–40 percent identities) than within one family. It is generally thought that proteins with about 30 percent sequence identity are likely to have similar three-dimensional structures; however, such high sequence identity is not required for proteins to share similar structures.

The kinship among homologous proteins is most easily visualized by a tree diagram (in essence, a family tree) based on sequence analyses. For example, the amino acid sequences of globins — the proteins hemoglobin and myoglobin and their relatives from bacteria, plants, and animals — suggest that they evolved from an ancestral monomeric oxygen-binding protein (Figure 3-12a). With the passage of time, the gene for this ancestral protein slowly changed due to random changes in the DNA sequence, initially diverging into lineages leading to animal and plant globins. Subsequent changes gave rise to myoglobin and, after a gene

duplication, to the α and β subunits of the tetrameric hemoglobin molecule ($\alpha_2\beta_2$) of the vertebrate circulatory system.

FIGURE 3-12 Evolution of protein families. (a) A primitive monomeric oxygen-binding globin is thought to be the ancestor of modern-day blood hemoglobins, muscle myoglobins, and plant leghemoglobins. Sequence comparisons have revealed that the evolution of the globin proteins parallels the evolution of animals and plants. Major changes occurred with the divergence of plant globins from animal globins and of myoglobin from hemoglobin. Later, gene duplication gave rise to the α and β subunits of hemoglobin. See R. C. Hardison, 1996, *Proc. Nat'l. Acad. Sci. USA* **93**:5675. (b) The family tree of 478 human protein kinases is divided into seven major groups of protein kinase families (comprising 405 kinases), designated: CMGC, CAMK, AGC, CK1, STE, TKL, and TK. Each of these contains families and subfamilies. We will describe the critical roles of kinases from many of these groups in subsequent chapters. For example, the members of the TK (tyrosine kinase) group are distinctive because they phosphorylate the side chains of tyrosine residues. One TK member is the receptor for the hormone insulin (Chapter 16).

[Part (b) Republished with permission of American Association for the Advancement of Science, from G. Manning et al., 2002, "The Protein Kinase Complement of the Human

Genome," *Science* **298**:1912–1934; permission conveyed through Copyright Clearance Center, Inc.]

A series of duplications and divergences can lead to the generation of a large, highly branched family of genes and corresponding proteins within a single organism. Figure 3-12b shows such a family tree for the 478 human protein kinase enzymes that evolved from one ancient precursor. All of these kinases catalyze the covalent addition of a phosphate group from ATP to the hydroxyl group of the side chains of serine, threonine, or tyrosine (∼15 percent phosphorylate tyrosines) (see Figure 2-15). A small number phosphorylate both serine (or threonine) and tyrosine are called *dual-specificity* kinases. Forty additional human kinases evolved from other precursors, and thus there is a total of 518 kinases in what is called the *human kinome*. In such a large family tree, the sum of the lengths of the lines between one member and another is generally proportional to the evolutionary distance between the two proteins — the shorter the distance on the tree between any two members of the family, the more similar they are in sequence and typically in structure and function. Often analysis of the branching patterns of proteins in such family trees is used to subdivide the members into groups, families, and subfamilies (Figure 3-12b) rather than relying on a precise formula using an arbitrary percent identity of sequence to define subfamilies, families, and so on.

There Are Four Broad Structural Categories of Proteins

Proteins usually fall into one of four broad structural categories based on their tertiary structure: *globular proteins, fibrous proteins, integral membrane proteins*, and *intrinsically disordered proteins*. These four broad categories of proteins are not mutually exclusive — some proteins are made up of combinations of segments that fall into two or more of these categories. *Globular proteins* are generally water-soluble, compactly folded structures, often spheroidal, that comprise a mixture of secondary structures (e.g., see Figure 3-9). *Fibrous proteins* are large, elongated, often stiff molecules. Some fibrous proteins are composed of a long polypeptide chain comprising many tandem copies of a short amino acid sequence motif that forms a single repeating secondary structure. These fibrous proteins are often made up of helical polypeptide chains, including α helices, triple helices (see the structure of collagen, the most abundant protein in mammals, in Figure 20-26) and helical coil coils with two or more strands (see Figure 3-7). Other fibrous proteins are composed of repeating globular protein subunits, such as the helical array of G-actin protein monomers that forms F-actin microfilaments (see Chapter 17). Fibrous proteins, which can aggregate into large multiprotein fibers that do not readily dissolve in water, usually play a structural role or participate in cellular movements. *Integral membrane proteins* are embedded within the phospholipid bilayer of the membranes that enclose cells and

organelles. Their membrane-spanning domains often comprise one or more ~20-residue long α helices and occasionally β barrels; they are discussed in detail in Chapter 10.

Regardless of a protein's category of tertiary structure, one or more segments of the protein may be *disordered* meaning that they do not form thermodynamically stable structures. Disordered protein segments are exceptionally flexible in conformation, and their flexibility appears to be key to their functional activities. Regions of disorder can provide flexible links, or tethers, between well-ordered regions of a protein; serve as binding sites for other proteins (Figure 3-13a); serve as sites of some types of post-translational protein modification [e.g., covalent addition of phosphate groups (phosphorylation) or sugars (glycosylation)]; serve as targets of protease digestion that regulates protein activity; inhibit the activity of the protein in which they are embedded (autoinhibition sites); or serve as signals for intracellular sorting of proteins (see Chapter 13). The activities of many proteins containing disordered segments are described in subsequent chapters. For example, phosphorylation of the disordered C-terminal domain (CTD) of RNA polymerase II (see Figure 8-12), which is composed of multiple repeats of a seven–amino acid sequence containing proline, threonine, and serine, regulates key steps in the synthesis of mRNA (see Chapters 8 and 9). The N-termini of histone proteins that control DNA organization in chromatin (see Chapter 7) are sites of important post-translational modifications, and the disordered, proline-rich FH1 region in the

protein formin controls the assembly of actin filaments (see Chapter 17).

Many proteins we consider in this book adopt only one or a few very closely related conformations when they are in their normal functional state, called the *native state*. However, in some proteins, the *entire* polypeptide chain is disordered. These proteins do not have well-ordered structures in their native, functional states; instead, their polypeptide chains are very flexible with no fixed conformation. These proteins are called *intrinsically disordered proteins (IDP)*. Intrinsically disordered proteins typically serve as signaling molecules, regulators of the activities of other molecules, or as scaffolds for multiple proteins, small molecules, and ions (e.g., binding ions via multiple charged residues). Disordered segments may also be present in otherwise well-structured proteins; these disordered segments are called **intrinsically disordered regions (IDR)**.

Intrinsically disordered proteins and disordered segments can be identified experimentally using various biochemical techniques, such as tests of sensitivity to protease digestion (disordered regions usually exhibit greater protease sensitivity), and a wide variety of biophysical techniques, including spectroscopy. The disorder of these protein segments or of an entire protein apparently arises as a consequence of their having a sequence that, relative to well-ordered proteins, is richer in polar amino acids, proline, and net

charge, and poorer in hydrophobic residues (Figure 3-13b). Algorithms primarily based on calculations of amino acid composition — particularly net charge and hydrophobicity — are used to predict which proteins or segments of proteins are disordered. By some estimates, about 30 percent or more of eukaryotic proteins have at least one segment of 50 or more consecutive residues that is disordered. In some cases, an intrinsically disordered protein (or region) can transition into a highly ordered structure (see Figure 3-13a).

EXPERIMENTAL FIGURE 3-13 Intrinsically disordered proteins: mechanisms of binding to well-ordered proteins and identification based on hydrophobicity and net charge. (a) The binding of an intrinsically disordered protein (PUMA, blue) to a well-ordered protein (MCL1, gray) results in the formation of a well-defined structure in the previously disordered protein. Two mechanisms have been proposed for generating a bound complex in which both proteins are structured: conformational selection (*top pathway*) and induced fit (*bottom pathway*). In conformational selection, the disordered protein (PUMA) occasionally and transiently adopts in solution the structure it would have in the bound state. The well-ordered binding partner (MLC1) can then bind to (select) PUMA in that transient, ordered conformation, forming a relatively stable bound complex. In induced fit, the disordered

protein begins to bind to the well-ordered partner while still disordered and then, while bound, is induced to form the ordered conformation present in the relatively stable, heterodimeric complex. Experiments suggest that the induced fit mechanism best describes the binding of PUMA and MCL1. (b) The sequences of 275 well-ordered, monomeric globular proteins (gray squares) and 91 intrinsically disordered proteins (black and yellow circles) were used to calculate the mean hydrophobicity per residue in each protein using a scale of 0 (least hydrophobic) to 1 (most hydrophobic, *x* axis), and the mean net charge per residue at pH 7.0 (*y* axis). With only three exceptions (black circles), the proteins define two distinct distributions: low hydrophobicity, high net charge (intrinsically disordered, yellow circles) and high hydrophobicity, low net charge (well-ordered, gray squares). The three disordered proteins (black circles) that overlap with the well-ordered population each contain substantial segments predicted to be disordered (low hydrophobicity, high net charge) that apparently overwhelm the rest of the proteins' sequences that might otherwise result in a well-ordered conformation.

Soc.* **135**(4):1415–1422; https://doi.org/10.1021/ja309527h. Part (b) Data from V. N. Uversky, J. R. Gillespie, and A. L. Fink, 2000, *Proteins* **41**:415–427.]

Multiple Polypeptides Assemble into Quaternary Structures, Supramolecular Complexes, and Biomolecular Condensates

Multimeric proteins consist of two or more polypeptide chains that in this context are referred to as *subunits*. A fourth level of structural organization, **quaternary structure**, describes the number (stoichiometry), relative positions, and often the tertiary structures

of the subunits in multimeric proteins. Multimeric proteins are composed of various numbers of identical (homomeric) or different (heteromeric) subunits, typically held together by noncovalent bonds. Flu virus hemagglutinin, for example, is a trimer of three identical subunits (a homotrimer) (see Figure 3-10). In many cases, the individual monomer subunits of a multimeric protein cannot function normally unless they are assembled into the multimeric protein. In other cases, assembly into a multimeric protein permits proteins that act sequentially in a pathway to increase their efficiency of operation owing to their juxtaposition in space, a phenomenon referred to as *metabolic coupling*. Classic examples of metabolic coupling are the fatty acid synthases of fungi, which are enzymes that synthesize fatty acids, and the polyketide synthases, which are large multiprotein complexes in bacteria that synthesize a diverse set of molecules called *polyketides* often used as drugs, including the antibiotic erythromycin.

Supramolecular Complexes

The highest level in the hierarchy of protein structure is the association of proteins into supramolecular complexes. Typically, such structures are very large, containing tens to hundreds of polypeptide chains and sometimes other biopolymers such as nucleic acids. In some cases, supermolecular structures exceed 1 megadalton (MDa) in mass, approaching 30–300 nm in size. The capsid that encases the nucleic acids of a viral genome is an

example of a supramolecular complex with a structural function. The bundles of cytoskeletal filaments that support and give shape to the plasma membrane are another example.

Other supramolecular complexes act as molecular machines. These complexes carry out complex cellular processes by integrating multiple proteins, each with distinct functions, into one large assembly. For example, a transcriptional machine is responsible for synthesizing messenger RNA (mRNA) using a DNA template. The operational details of this transcriptional machine are discussed in Chapters 5 and 8. It consists of RNA polymerase, itself a multimeric protein, and at least 50 additional components, including general transcription factors, promoter-binding proteins, helicase, and other protein complexes (Figure 3-14). Ribosomes, also discussed in Chapter 5, are complex machines that synthesize proteins and are formed of multiple proteins and nucleic acids. One of the most complex multiprotein assemblies is the nuclear pore, a structure that allows macromolecules to pass between the nucleus and the cytoplasm (see Chapter 13). It is composed of multiple copies of about 30 distinct proteins and forms an assembly with an estimated mass of 50 MDa. The fatty acid synthases and polyketide synthases referred to above are also molecular machines, as is the mitochondrial *supercomplex* $I/III_2/IV$ that integrates multiple steps in the electron-transport chain that provides energy for synthesizing ATP. This supercomplex (Figure 12-23) comprises three

supramolecular complexes and more than 64 polypeptide chains (see Chapter 12).

FIGURE 3-14 A molecular machine: the transcription initiation complex. The core RNA polymerase, general transcription factors, a mediator complex containing about 20 subunits, and other protein complexes not depicted here assemble at a promoter in DNA prior to the synthesis of the corresponding RNA. The polymerase carries out transcription of DNA; the associated proteins are required for initial binding of the polymerase to a specific promoter. Note that the DNA is bent in the transcription preinitiation complex. The multiple components function together as a molecular machine.

Biomolecular Condensates

A rather different approach to organizing together large collections of macromolecules is the generation of **biomolecular condensates** that are likely to play important roles in multiple aspects of cell biology. Biomolecular condensates are membraneless compartments in cells, often compared to liquid droplets, that are chemically and physically distinct from their surroundings. In biomolecular condensates, multiple copies of one or more macromolecules separate from the bulk surrounding fluid in a process called *liquid-liquid phase separation*. Through such phase separation, macromolecules, often proteins or proteins combined with RNAs, assemble or condense into a region of higher concentration than in the bulk surrounding fluid of the cytosol or nucleoplasm (Figure 3-15). Unlike the supramolecular complexes described above, biomolecular condensates can vary in size (100s to 1000s of nanometers), and their components generally do not have a fixed stoichiometry or quaternary structural arrangement.

EXPERIMENTAL FIGURE 3-15 Multivalent proteins with intrinsically disordered regions and other characteristics can assemble into biomolecular condensates. (a) Cells contain a variety of membraneless condensates, resembling liquid droplets, in the cytoplasm and nucleus (colored circles, *left*). Macromolecules (small circles in expanded rectangle before condensation, *upper right*) separate from the bulk surrounding fluid and concentrate in a biomolecular condensate due to liquid-liquid phase separation (large green circle after condensation, *lower right*). These macromolecules can diffuse into and out of the condensate (red arrows). (b) Models of the fruit fly (*Drosophila melanogaster*) proteins APC2 and Axin, two large proteins that participate in the Wnt signaling pathway (see Chapter 16). Many other species, including mammals, express APC2 and Axin homologues. These multivalent proteins contain domains (rectangles and squares), intrinsically disordered regions (black lines), and short sequence motifs (triangles) that perform key functions. The motifs designated by yellow triangles are involved with binding additional Wnt-associated signaling molecules (Chapter 16). When APC2 and Axin are synthesized in cultured cells with covalently attached fluorescent proteins (ovals), they can be visualized using confocal

fluorescence microscopy (Chapter 4). Each protein can oligomerize into larger complexes via the domains indicated by green brackets. (c) When expressed together, APC2 and Axin bind to each other [sites of binding indicated by blue dotted lines in panel (b)] forming biomolecular condensates that contain both proteins (both colors found in all condensates of various sizes, green GFP:APC2 on the *left*, red Axin:RFP on the *right*). (d) Two multivalent, artificial proteins, one of which is fluorescent (green) and can be easily detected by microscopy, were expressed together in human cells. These two proteins, which reside in the cytoplasm, cannot bind to one another unless the fluorescent protein is phosphorylated by the enzyme Protein Kinase A (PKA, see Section 3.4 and Chapter 15). In the absence of the hormone isoprenaline (*left panel*, 0 seconds with hormone), PKA is inactive, the two proteins do not bind to one another, and the green fluorescent protein is dispersed throughout the cytosol (*left panel*). In this condition, the proteins do not enter the nucleus (red ovals in the centers of the cells, the DNA was stained red by a fluorescently labeled DNA-binding protein called *histone 2B*, see Chapter 7). Addition of isoprenaline for 100 seconds (*right panel*) activates PKA, resulting in phosphorylation of the fluorescent protein, binding of the two proteins and formation in the cytosol of biomolecular condensates in which the proteins are concentrated (green dots that are brighter than the dispersed green in the *left panel*).

A biomolecular condensate can be thought of as an alternative to membrane-bound organelles (such as the ER, Golgi apparatus, lysosome, or a mitochondrion; see Chapter 1) for concentrating molecules in a defined region of the cell to facilitate integrated regulation of various cellular activities in time and space. We shall see in Chapter 14 that membrane-bound compartments, such as small transport vesicles, can fuse together to mix their contents and

that such vesicles can bud off, or break away from, larger structures (e.g., membrane vesicles break away from the ER and subsequently fuse with the Golgi apparatus). Biomolecular condensates can also break apart into smaller liquid droplets (disperse) or fuse (coalesce) into larger ones, just like drops of oil in water, such as in salad dressing. They also have the potential to undergo phase transitions from disordered liquid to a more highly ordered gel or even a solid-like state.

The capacity of a protein to form a condensate depends on its structure and concentration and on the conditions in its surrounding fluid, like pH, ionic strength, temperature, and the presence of other molecules. Within a cell, a set of such conditions is sometimes called the *physiologic state* of the cell. Thus alterations in conditions inside the cell appear to be able to regulate the formation of condensates. One characteristic of macromolecules that form biomolecular condensates is that they are multivalent — they have multiple sites that are able to bind to other molecules. In particular, they contain multiple domains that have the ability to bind to regions of other proteins or nucleic acids. When a protein binds to other copies of the same protein, it is said to oligomerize and the binding sites are called *oligomerization sites*. Another key characteristic of many proteins that form biomolecular condensates is that they have intrinsically disordered regions. The amino acid sequence of an IDR can influence the probability of a protein participating in the formation of a condensate and the nature of the

condensate formed. Currently, however, it can't be assumed that a protein having multiple domains or intrinsically disordered segment(s) will definitely incorporate into a condensate in vivo, but these features appear to play key roles for those proteins that do.

It is possible to readily detect condensates in cells using fluorescence microscopy (see Chapter 4) when one or more of the components contains a covalently attached fluorescent molecule. For example, in the Wnt signaling pathway that is described in detail in Chapter 16, several proteins assemble into biomolecular condensates, including two called *APC2* and *Axin* that are multivalent and have multiple protein-binding domains and IDRs (see Figure 3-15b). In the experiment shown in Figure 3-15c, the fluorescently labeled versions of the *Drosophila melanogaster* APC2 (fluoresces green) and Axin (fluoresces red) were expressed together in mammalian cells and assembled into nearly spherical condensates that contain both fluorescent molecules.

The types of proteins (and in some cases RNAs) that assemble to form a condensate control the properties of the condensate, as can the external conditions (pH, etc.). For example, Figure 3-15d shows cells that express two artificial proteins designed to form condensates. One of these is fluorescently labeled. In untreated cells the two cannot assemble into a condensate, so the fluorescent protein is distributed evenly throughout the cytosol (*left panel*, 0 sec, relatively low green fluorescence intensity). After stimulation with a

hormone for 100 seconds (*right panel*), the fluorescent protein is chemically modified (phosphorylated by an enzyme called a *kinase*; described in Section 3.4). As a consequence, it can then assemble with the other protein, which has a phosphoprotein-binding domain, into easily detected condensates (*right*, punctate green droplets that are especially bright because the concentration of the fluorescent molecules in the condensates is greater than when they are distributed through the cytosol). The condensates fuse into larger droplets as the incubation proceeds. The presence in a cell of spherical structures that (1) can fuse and break apart dynamically and (2) have components that can rapidly diffuse within the sphere and diffuse between the sphere and the surrounding liquid provides evidence that the labeled molecule participates in condensate formation. Examples of biomolecular condensates include nucleoli (sites of ribosomal subunit synthesis; Chapter 9), P-bodies (sites of translational repression and mRNA degradation; Chapter 9), and signaling complexes such as in the Wnt pathway (Chapter 16).

KEY CONCEPTS OF SECTION 3.1

Hierarchical Structure of Proteins

- Proteins are linear polymers of amino acids linked together by peptide bonds. A protein can have a single polypeptide chain or multiple polypeptide chains. There are four levels of organization of protein structure: primary, secondary, tertiary, and quaternary. The primary structure of a polypeptide chain is the sequence of covalently linked amino acids that compose the chain. Various mostly noncovalent interactions between amino acids in the linear sequence stabilize a protein's specific folded three-dimensional structure or conformation.

- Secondary structures are stabilized by hydrogen bonds between atoms of the peptide backbone. The α helix, β strand and sheet, and β turn are the most prevalent elements of protein secondary structure (see Figures 3-4, 3-5, and 3-6). Certain combinations of secondary structures give rise to structural motifs, which are found in a variety of proteins and are often associated with specific functions (see Figure 3-7).
- Protein tertiary structure results from hydrophobic interactions between nonpolar side groups and from hydrogen bonds and ionic interactions involving polar side groups and the polypeptide backbone. These interactions stabilize the folding of a polypeptide chain, including its secondary structural elements and structural motifs, into an overall three-dimensional arrangement.
- Proteins often contain distinct domains, independently folded regions with characteristic structural, functional, or topological properties.
- The incorporation of domains as modules in different proteins in the course of evolution has generated diversity in protein structure and function.
- Proteins with similar amino acid sequences generally can be assumed to have similar three-dimensional structures and similar functions. There are also examples of polypeptide chains with dissimilar sequences folding into similar three-dimensional structures.
- Homologous proteins are proteins that evolved from a common ancestor and thus have similar sequences, structures, and functions. They can be classified into families and superfamilies.
- Entire proteins or segments of proteins usually fall into one of four broad structural categories: globular proteins, fibrous proteins, integral membrane proteins, and intrinsically disordered proteins.
- The exceptional conformational flexibilities of intrinsically disordered proteins contribute to their functions as binding partners, signaling molecules, regulators of other molecules, scaffolds, flexible links between well-ordered regions of a protein, sites of post-translational protein modification, autoinhibitors, and signals for intracellular protein sorting.
- The quaternary structure of a protein is defined by the number (e.g., dimer or trimer) and organization of individual polypeptide subunits assembled into a multimeric protein.
- Cells contain large supramolecular complexes, sometimes called *molecular machines*, in which dozens of polypeptide chains assemble to perform complex cellular processes (e.g., DNA, RNA, and protein synthesis; photosynthesis; ATP generation, signal transduction).
- Biomolecular condensates are large, dynamic assemblies of molecules that form membraneless compartments. These liquid droplet-like condensates are chemically and physically distinct, or phase-separated, from the bulk surrounding fluid (e.g.,

cytosol or nucleoplasm). The capacity of proteins to form condensates depends on their structures and the surrounding environment (pH, temperature, etc.). Condensate-forming proteins often contain multiple binding domains (they are multivalent) and intrinsically disordered regions.

3.2 Protein Folding

As noted previously, when it comes to the architecture of proteins, "form follows function." Thus for a polypeptide to fulfill its biological role within or outside cells, it is essential that it be synthesized with the proper amino acid sequence, and that it fold into the proper three-dimensional conformation, with the appropriate secondary, tertiary, and possibly quaternary structure. How is a protein with a proper sequence generated? A polypeptide chain is synthesized by a complex process called *translation*, which occurs in the cytoplasm on a large protein–nucleic acid complex called a *ribosome*. During translation, a sequence of *messenger RNA* (*mRNA*) serves as a template for the assembly of a corresponding amino acid sequence. The mRNA is initially generated by a process called *transcription*, whereby a nucleotide sequence in DNA is converted by transcriptional machinery in the nucleus into a sequence of mRNA. The intricacies of transcription and translation are considered in Chapter 5. Here we describe the key factors that ensure that a newly formed or forming (nascent) polypeptide chain is properly folded as it emerges from the ribosome.

Planar Peptide Bonds Limit the Shapes into Which Proteins Can Fold

A critical structural feature of polypeptides that limits how the chain can fold is the planar structure of the peptide bond. Figure 3-3 illustrates the amide group in peptide bonds in a polypeptide chain. Because the peptide bond itself behaves somewhat like a planar double bond, the portions (X and Y) of the polypeptide chain on either side of the peptide bond can be oriented in either a trans or cis configuration relative to the peptide bond.

We saw similar cis and trans isomers of carbon-carbon double bonds in unsaturated fatty acids in Chapter 2. Analysis of crystal structures indicates that in proteins, about 99.97 percent of the peptide bonds that have any residue other than proline at Y are in the trans configuration. (We will consider those with proline at Y shortly.) In a peptide bond, the carbonyl carbon and amide nitrogen and those atoms directly bonded to them must all lie in a fixed plane (Figure 3-16); little rotation about the peptide bond itself is possible. Yet a polypeptide chain must be flexible, able to twist and turn — and thus fold into different three-dimensional shapes. The only flexibility in a polypeptide chain itself is rotation of the fixed planes of adjacent peptide bonds with respect to one another about two

bonds: the C_α–amino nitrogen bond (rotational angle called Φ) and the C_α–carbonyl carbon bond (rotational angle called Ψ).

FIGURE 3-16 Rotation between planar peptide groups in proteins. In a peptide bond, the carbonyl carbon and amide nitrogen and those atoms directly bonded to them all lie in a fixed plane (orange rectangles). Rotation is possible about the C_α–amino nitrogen bond (the Φ angle) and the C_α–carbonyl carbon bond (the Ψ angle).

Through this rotation polypeptide backbones are able, in principle, to adopt a very large number of potential conformations. However, steric restraints due to the structure of the polypeptide backbone and the properties of the amino acid side chains dramatically restrict the potential conformations that any given protein can assume.

A further constraint imposes additional limits on the potential conformations that a polypeptide chain can adopt. Only a limited number of Φ and Ψ angles are possible because, for most Φ and Ψ angles, the backbone or side-chain atoms would come too close to one another, and thus the associated conformation would be highly unstable or even physically impossible to achieve.

Protein Folding Is Promoted by Proline Isomerases

As we have seen, the portions of the polypeptide chain on either side of a peptide bond (X and Y) are almost always oriented in a trans configuration (Figure 3-17a). However, the trans configuration is not dramatically more energetically favorable than a cis configuration when there is a proline at Y (Figure 3-17b). Among those folded proteins whose structures have been determined, about

5–7 percent of peptide bonds with proline at Y exhibit the cis configuration, as compared with 0.03 percent of all other peptide bonds without proline at Y.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 3-17 Proline cis/trans isomerizations influence protein folding and structure. (a) Due to the planar, double bond–like character of peptide bonds, the portions of the polypeptide chain on either side (X and Y) may have cis or trans configurations. The trans configuration is present in about 99.97 percent of all peptide bonds in well-ordered proteins when Y is a residue other than proline. (b) When Y is proline, about 5–7 percent of peptide bonds are in the cis configuration. Proline isomerases catalyze the cis/trans isomerization to facilitate protein folding. (c) The structure of a portion of a protein, here an SH2 protein domain (see Chapter 16), can be dramatically altered by the cis/trans isomerization of a single proline, and this structural change can influence the protein's activity.

[Part (c) Trans data from E. V. Pletneva et al., 2006, *J. Mol. Biol.* **357**:550–561, PDB ID 2etz; cis data from R. J. Mallis et al., 2002, *Nat. Struct. Biol*. **9**:900–905, PDB ID 1lui.]

The spontaneous rate of isomerization between the cis and trans configurations of proline-containing peptide bonds is relatively slow (milliseconds to seconds), whereas many protein-folding events occur more quickly (microseconds to milliseconds). Thus cells use peptidyl-proline isomerase (PPIases) proteins to catalyze these cis/trans isomerizations so that the proline in the folding protein quickly forms the proper isomer. Cis/trans isomerization of proline also can act as a switch to alter the conformation, and thus the activity, of an already stably folded protein. Indeed, such isomerizations can substantially alter the structure of some proteins (Figure 3-17c). Humans have 45 different PPIases that catalyze these critical folding and conformational switch reactions.

The Amino Acid Sequence of a Protein Determines How It Will Fold

While the constraints of backbone bond angles seem very restrictive, any polypeptide chain containing only a few residues could, in principle, still fold into many conformations. For example, if the Φ and Ψ angles were limited to only 8 combinations, an n-residue-long peptide would potentially have 8^n conformations; for even a small polypeptide of only 10 residues, that's about 8.6 million possible conformations! In general, however, the native state of any particular protein that is not intrinsically disordered adopts only one or a few very closely related conformations; for the vast majority of these proteins, the native state is a stably folded form of the molecule and the one that permits it to function normally. In thermodynamic terms, the native state is usually the conformation with the lowest free energy (G) (see Chapter 2).

What features of natively well-ordered proteins limit their folding from so many potential conformations to just one or a few? The properties of the side chains (e.g., size, hydrophobicity, charge, ability to form hydrogen and ionic bonds), together with their particular sequence along the polypeptide backbone, impose key restrictions. For example, a large side chain, such as that of tryptophan, might sterically block one region of the chain from packing closely against another region, whereas a side chain with a positive charge, such as that of arginine, might attract a segment of

the polypeptide that has a complementary negatively charged side chain (e.g., aspartic acid). Another example we have already discussed is the effect of the aliphatic side chains in heptad repeats in promoting the association of helices and the consequent formation of coiled coils. *Thus a polypeptide's primary structure determines its secondary, tertiary, and quaternary structures*.

The initial evidence that the information necessary for a protein to fold properly is encoded in its amino acid sequence came from in vitro (in test tubes) studies on the refolding of purified proteins, especially the Nobel Prize–winning studies in the 1960s by Christian Anfinsen of the refolding of ribonuclease A, an enzyme that cleaves RNA. Others had previously shown that various chemical and physical perturbations can disrupt the weak noncovalent interactions that stabilize the native conformation of a protein, leading to the loss of its normal tertiary structure. The disruption of a protein's structure (and this can include secondary as well as tertiary structure) is called **denaturation**. Denaturation can be induced by thermal energy from heat, extremes of pH that alter the charges on amino acid side chains, or exposure to *denaturants* such as urea or guanidine hydrochloride at concentrations of 6–8 M, all of which disrupt structure-stabilizing noncovalent interactions. Treatment with reducing agents, such as β-mercaptoethanol, that break disulfide bonds can further destabilize disulfide-containing proteins. Under denaturing conditions, a population of uniformly folded protein molecules is destabilized and converted into a

collection of many unfolded, or denatured, molecules that have many different non-native and biologically inactive conformations. As we have seen, a large number of possible non-native conformations exist (e.g., $8^n - 1$). Two broad classes of non-native conformations are seen in proteins: (1) monomeric unfolded or denatured structures and (2) aggregates, which can either be amorphous or have a well-organized structure, as is the case for the disease-associated amyloid fibrils described later in this chapter. In principle, aggregates can comprise many copies of a single protein (homogeneous aggregates) or contain a mixture of distinct proteins (heterogeneous aggregates).

The spontaneous unfolding of proteins under denaturing conditions is not surprising, given the substantial increase in entropy that occurs because a denatured protein can adopt many non-native conformations (increased disorder). What is striking, however, is that when a pure sample of a single type of unfolded protein in a test tube is shifted back very carefully to normal conditions (body temperature, normal pH levels, reduction in the concentration of denaturants), some denatured polypeptides can spontaneously refold into their native, biologically active states, as in Anfinsen's experiments. This kind of refolding experiment, as well as studies showing that proteins synthesized in a test tube can fold properly, established that the information contained in a protein's primary structure can be sufficient to direct correct refolding. Newly synthesized proteins appear to fold into their proper conformations

just as denatured proteins do. The observed similarity in the folded, three-dimensional structures of proteins with similar amino acid sequences, noted in Section 3.1, provided additional evidence that the primary sequence also determines protein folding in vivo (in live organisms). It appears that secondary structures and structural motifs form early in the folding process, followed by assembly of more complex structural domains, which then associate into more complex tertiary and quaternary structures (Figure 3-18).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 3-18 Hypothetical protein-folding pathway. Folding of a monomeric protein follows the structural hierarchy of primary (a) → secondary (b–d) → tertiary (e) structure. Formation of small structural motifs (c) appears to precede formation of domains (d) and the final tertiary structure (e).

Folding of Proteins In Vivo Is Promoted by Chaperones

The conditions under which a purified, denatured protein refolds in a test tube differ markedly from the conditions under which a newly synthesized polypeptide folds in a cell. The presence of other biomolecules, some of which are themselves nascent and in the process of folding, can potentially interfere with the autonomous, spontaneous folding of an otherwise natively well-ordered protein by forming aggregates. The cytosolic concentrations of some proteins are very high, and the total cytosolic protein concentration

can be ~300 mg/ml in mammalian cells. These high-protein concentrations favor the formation of aggregates by increasing the chances a nascent protein will encounter other proteins prior to completing its folding. Unfolded and partly folded proteins tend to aggregate into large, often water-insoluble masses, from which it is extremely difficult for a protein to dissociate and then fold into its proper conformation on its own. In part, this aggregation is due to the exposure of hydrophobic side chains that have not yet had a chance to be buried in the inner core of the folded protein. Exposed hydrophobic side chains on different molecules will stick to one another, owing to the hydrophobic effect (see Chapter 2) and thus promote aggregation. The risk of such aggregation is especially high for newly synthesized proteins that have not yet completed their proper folding. Intrinsically disordered proteins are much less likely to form such deleterious aggregates because, at least in some cases, they have relatively fewer hydrophobic side chains. Although some proteins can fold into a well-ordered native state in vitro, not all unfolded molecules are able to fold properly in a timely fashion because of the very large number of potentially incorrect, intermediate conformations into which the protein might fold.

Given such impediments, cells require faster, more efficient mechanisms for folding natively well-ordered proteins into their correct shapes than sequence alone provides. Without such help, cells might waste much energy in the synthesis of improperly folded, nonfunctional proteins, which would have to be destroyed to

prevent their disrupting cell function. Cells clearly have such mechanisms, since more than 95 percent of the proteins present within cells have been shown to be in their native conformations. Proteins that do not or cannot fold properly — for example, those encoded by genes with mutations that alter the amino acid sequence — are often recognized as unfolded and rapidly degraded by enzymes.

The explanation for the cell's remarkable efficiency in promoting proper protein folding is that cells make a set of proteins, called **chaperones**, that facilitate proper folding of nascent proteins. One way that chaperones facilitate proper folding is that they prevent aggregation by binding to the target polypeptide or sequestering it from other partially or fully unfolded proteins, thereby giving the nascent protein time to fold properly without colliding into other unfolded proteins. The importance of chaperones is highlighted by the observation that many are evolutionarily conserved. Chaperones are found in all organisms from bacteria to humans, and some are homologs with high sequence similarity that use almost identical mechanisms to assist protein folding. In eukaryotes, chaperones are located not only in the cytosol but also within organelles, like the endoplasmic reticulum, mitochondria, and the nucleus.

Chaperones help fold newly made proteins into functional conformations or refold misfolded or unfolded proteins into functional conformations. Sometimes in a cycle of chaperone-assisted protein folding, the details of which are described below,

the target protein fails to adopt a mature, stable conformation. Chaperones can then re-engage with the target for additional cycles of chaperone-mediated folding until proper folding is achieved. Chaperones can also disassemble potentially toxic protein aggregates that form due to protein misfolding; assemble and dismantle large multiprotein complexes; and mediate transformations between inactive and active forms of some proteins (such as the open and closed forms of some protein kinases, which we discuss shortly). Thus chaperones are very important!

Chaperones bind to the target proteins — also called *substrates* or *client proteins* — whose folding they will assist. Chaperones use a cycle of ATP binding, ATP hydrolysis to ADP, and exchange of a new ATP molecule for the ADP to induce a series of conformational changes that are essential for their function. There are several different classes of chaperones with distinct structures, but all use ATP binding and hydrolysis in a variety of ways, which include (1) to enhance the binding of the target protein and (2) to switch their own conformation. This ATP-dependent conformational switching is used in turn (1) to optimize folding, (2) to return the chaperone to its initial state so that it is available to help fold another molecule, and (3) to set the time permitted for refolding, which can be determined by the rate of ATP hydrolysis.

Two general families of chaperones have been identified:

- Molecular chaperones, which bind to a short segment of a protein substrate and stabilize unfolded or partly folded proteins, thereby preventing these proteins from aggregating and being degraded. Molecular chaperones bind to the nascent chain of a protein as it is synthesized and as it exits the ribosome and therefore begin binding to a new protein even before its synthesis is complete (see Chapter 13).
- Chaperonins, which form folding chambers into which all or part of an unfolded protein can be sequestered, giving it time and an appropriate environment to fold properly.

Molecular Chaperones

Two major types of molecular chaperone are Hsp70 and Hsp90. The substrates of Hsp70 are unfolded proteins, such as newly synthesized proteins. Hsp70 can function in concert with Hsp90 to help fold partially folded proteins or to remodel or otherwise change the conformation of certain folded proteins. The mechanisms by which Hsp70 and Hsp90 participate in folding other proteins are shown in Figure 3-19.

FIGURE 3-19 Protein folding mediated by molecular chaperones. (a) Many proteins fold into their proper three-dimensional structures with the assistance of Hsp70 or one of several Hsp70-like proteins. These molecular chaperones transiently bind to a nascent polypeptide as it emerges from a ribosome or to a protein that is unfolded. In the Hsp70 cycle, an unfolded substrate protein binds in equilibrium (step 1) to Hsp70's substrate-binding site (red) in the open conformation of its substrate-binding domain (light and dark orange) when an ATP (purple) is bound at Hsp70's nucleotide-binding domain (light blue). The substrate-binding domain comprises two subdomains (light and dark orange) that change relative positions and conformations during the cycle. Co-chaperone accessory proteins (DnaJ/Hsp40) stimulate the hydrolysis of ATP to ADP (yellow) that induces a large conformational change in the substrate-binding domain, resulting in the closed conformation, in which the substrate is tightly locked into the substrate-binding domain, preventing inappropriate folding or aggregation (steps 2 and 3). Exchange of cytosolic ATP for the bound ADP, stimulated by other accessory, co-chaperone proteins (GrpE/BAG1), converts the Hsp70 back to the open conformation (step 4), releasing the substrate and freeing it to continue folding (step 5). With the substrate released, Hsp70 can then interact with additional substrates. If the released substrate does not fold properly, it can rebind to another chaperone and the process is repeated. (b) In many, but not all, cases, a substrate protein partially folded by Hsp70 will be transferred to Hsp90 for further folding. Three conformational states of the dimeric Hsp90 molecular chaperone are thought to be involved

in substrate (also called *client*) protein remodeling. Client proteins bind at the substrate-binding site (red surface) shared by the substrate-binding (orange) and C-terminal dimerization (white) domains and are thought to change conformation in response to ATP binding and hydrolysis. The Hsp90 cycle begins when there is no nucleotide bound to the nucleotide-binding domains (light blue) and the dimer is in a very flexible, open configuration (step **1**) that can bind a client. Rapid ATP binding leads to a conformational change (step **2**) in which the nucleotide-binding domains and the substrate-binding domains move together (intermediate shown in step **3**) into a closed conformation in which the nucleotide-binding domains are bound to each other (step **4**). With Hsp90 in its closed conformation, the client protein may undergo folding. In some cases, when a folded protein is bound to the closed Hsp90 (step **4**) it can undergo a conformational change. The precise locations in Hsp90 at which clients bind apparently vary for different clients. ATP hydrolysis results in a conformational change in Hsp90 (step **5**) that may include a highly compact form, folding of the client, client protein release and additional folding of the unbound client. The ADP-bound form of Hsp90 can adopt several conformations, including a highly compact form. Release of ADP (step **6**) completes the cycle by regenerating the initial flexible open state, which can then interact with additional clients. The order of substrate release, ATP hydrolysis, and ADP release remain to be established definitively. See E. D. Kirschke et al., 2014, *Cell* **157**:1685; and M. Taipale, D. F. Jarosz, and S. Lindquist, 2010, *Nat. Rev. Mol. Cell Biol.* **11**:515.

Hsp70

The heat-shock protein Hsp70 in the cytosol and its homologs were first identified by their rapid appearance after a cell had been stressed by an increase in temperature, that is, heat shock (*Hsp* stands for "*h*eat-*s*hock *p*rotein"). The homologs of cytosolic Hsp70 include Hsp70 in the mitochondrial matrix, BiP in the endoplasmic reticulum, and DnaK in bacteria. Hsp70 and its homologs are the

major chaperones in all organisms that use an ATP-dependent cycle to facilitate proper folding of their substrates (Figure 3-19a). The five steps in the Hsp70 cycle are:

1. Substrate binding to the "open" ATP-bound Hsp70.
2. Substrate binding induces ATP hydrolysis to ADP that leads to a "closed" ADP-bound Hsp70 conformation that binds substrate much more tightly.
3. Inhibition of substrate misfolding or aggregation while bound tightly to the closed Hsp70. In a sense, Hsp70 acts by inhibiting inappropriate protein folding.
4. Exchange of ATP for ADP on the Hsp70 with its conversion to the "open" conformation.
5. Release of the substrate protein and its subsequent folding.

If the target is now properly folded, it cannot rebind to an Hsp70. If it remains at least partially unfolded, it can bind again to give a chaperone another chance to help fold it properly. A variety of co-chaperone proteins facilitate this process. As we will see later in this chapter, a variety of proteins use a cycle of trinucleotide hydrolysis to a dinucleotide, followed by dinucleotide/trinucleotide exchange, to control their activities. We will discuss a group of proteins called *GTPases* that depend on the exchange of GTP, rather than ATP, for bound GDP (instead of ADP) to induce conformational changes that dramatically influence the proteins' activities and the subsequent hydrolysis of the bound GTP to GDP.

Additional proteins, such as the co-chaperone Hsp40 in eukaryotes (DnaJ in bacteria), help increase the efficiency of the Hsp70-mediated folding of many proteins not only by stimulating the binding of substrate but also by increasing the rate of hydrolysis of ATP by 100- to 1000-fold (see step **2** in Figure 3-19a). Members of four different families of nucleotide exchange factors (e.g., GrpE in bacteria; BAG, HspBP, and Hsp110 in eukaryotes) also interact with Hsp70 (or DnaK in bacteria), promoting the exchange of ATP for ADP (see step **4**). Multiple molecular chaperones are thought to bind to all nascent polypeptide chains as they are being synthesized on ribosomes. In bacteria, 85 percent of the proteins are released from their chaperones and proceed to fold normally; an even higher percentage of proteins in eukaryotes follow this pathway.

Hsp90

Hsp90-family molecular chaperones usually recognize partially folded substrate proteins, generally called *clients*. Evolutionarily related Hsp90 family members are present in all organisms except archaea. Their strong evolutionary conservation is seen in the high amino acid sequence similarity (55 percent) of the Hsp90 from the bacterium *Escherichia coli* and human Hsp90. In most eukaryotes, there are four distinct Hsp90s: two in the cytosol and one each in the endoplasmic reticulum and the mitochondrion. At 1–2 percent of total protein, Hsp90 is one of the most abundant cytosolic proteins. Although the range of protein substrates for Hsp90 chaperones is

not as broad as for some other chaperones (at least 10 percent of yeast proteins are thought to be Hsp90 substrates), the Hsp90s are essential in eukaryotes. The Hsp90s help cells fold partially folded clients (see Figure 3-19b), cope with denatured proteins generated by stress (e.g., heat shock), and ensure that some of their clients can be converted from an inactive to an active state or otherwise held in a functional conformation. In some cases, an Hsp90 forms a relatively stable complex with a client until an appropriate signal causes it to dissociate, freeing the client to perform some regulated function in the cell. Hsp90 clients include transcription factors such as the receptors for many steroid hormones, like estrogen and testosterone. These steroid receptors regulate sexual development and function by controlling the activities of many genes (see Chapter 8). Another type of Hsp90 client is the set of enzymes called *kinases*, which control the activities of many other proteins by phosphorylation (see Section 3.4 and Chapters 15 and 16).

Unlike monomeric Hsp70, Hsp90 functions as a dimer in a cycle in which ATP binding, hydrolysis, and ADP release are coupled to major conformational changes and to binding, folding or activation, and release of clients (see Figure 3-19b). Although much about the mechanism of Hsp90 remains to be learned, it is clear that partially folded clients bind to the substrate-binding domains when the chaperone is in the "open" conformation (step **1** in Figure 3-19b), that ATP binding leads to interaction of the ATP-binding domains and formation of a "closed" conformation (steps **1**–**4** in Figure 3-

19b), and that hydrolysis of ATP plays an important role in the activation of some client proteins and their subsequent release from the Hsp90 (steps **5** and **6**). The order of substrate release, ATP hydrolysis and ADP release remain to be established definitively. We also know that there are at least 20 co-chaperones that can profoundly affect the activity of Hsp90, including modulating its ATPase activity and determining which proteins will be clients (client specificity). Co-chaperones can also help coordinate the activities of Hsp90 and Hsp70. For example, Hsp70 can help begin the folding of a client that is then handed off by a co-chaperone to Hsp90 for additional processing. Hsp90 activity can also be influenced by its covalent modification by small molecules. Finally, Hsp90 can help cells recognize misfolded proteins that are unable to refold and facilitate their degradation by mechanisms discussed later in this chapter. Thus, as part of the quality-control system in cells, molecular chaperones can help proteins fold properly or facilitate the destruction of those that cannot fold properly. In some cases, Hsp70s, Hsp90s, and their co-chaperones can bind to their clients in a well-defined order during the folding process.

Chaperonins

The proper folding of a large variety of newly synthesized proteins also requires the assistance of another class of proteins, the chaperonins, also called *Hsp60s*. Chaperonins are huge cylindrical supramolecular assemblies. In the center of chaperonins are

chambers into which all or part of an unfolded protein enters. The chambers provide an environment conducive to protein folding that occurs in the context of cycles of ATP binding and hydrolysis and the opening and closing of lids that seal the chambers during the folding process, as described below. The folding chambers are formed from two rings of oligomers. There are two distinct groups of chaperonins that differ somewhat in their structures, detailed molecular mechanisms, and locations. Group I chaperonins are found in prokaryotes, chloroplasts, and mitochondria. They are composed of two rings, each having seven subunits that interact with a co-chaperone *lid* that also has seven subunits. Each ring is a folding chamber into which an unfolded protein enters. The bacteria group I chaperonin, known as *GroEL/GroES*, is shown in Figure 3-20a. In the bacterium *E. coli*, GroEL is thought to participate in the folding of about 10 percent of all proteins. Group II chaperonins are found in the cytosol of eukaryotic cells and in archaea. These chaperonins can have eight to nine homomeric or heteromeric subunits in each ring, and the lid function is incorporated into those subunits themselves — no separate lid protein is needed. It appears that ATP hydrolysis triggers the closing of the lid of group II chaperonins.

FIGURE 3-20 Protein folding mediated by chaperonins. Proper folding of some proteins depends on chaperonins, such as the prokaryotic group I chaperonin GroEL and the group II chaperonin TRiC. (a) GroEL is a barrel-shaped complex of fourteen identical ~60,000-MW subunits, arranged in two stacked rings (blue) of seven subunits each that form two distinct internal polypeptide folding chambers. GroES lids (red) of seven identical subunits can bind to either end of the barrel and seal the chamber on that side (cutaway view on the right). (b) The GroEL-GroES folding cycle. A partly folded or misfolded polypeptide enters one of the folding chambers (step 1). The second chamber is blocked by a GroES lid. Each ring of seven GroEL subunits binds seven ATPs, hydrolyzes them, and then releases the ADPs in a set order coordinated with GroES binding and release and polypeptide binding, folding, and release. The major conformational changes that take place in the GroEL rings control the binding of the GroES lid that seals the chamber (step 2). The polypeptide remains encased in the chamber capped by the lid, where it can undergo folding until ATP hydrolysis — the slowest, rate-limiting step in the cycle ($t_{1/2}$~10 s) (step 3) — induces binding of ATP and a different GroES to the other ring (transient intermediate shown in brackets). This binding then causes the GroES lid and ADP bound to the peptide-containing ring to be released, opening the chamber and permitting the folded protein to diffuse out of the chamber (step 4). If the polypeptide has folded properly, it can proceed to function in the cell. If it remains partially folded or misfolded, it can rebind to an unoccupied GroEL and the cycle can be repeated. See D. L. Nelson and M. M. Cox, 2013, *Lehninger Principles of Biochemistry*, 6th ed., Macmillan. (c) CryoEM structures of lid open (top) and lid closed (bottom) yeast TRiC. Two hetero-octamers form the upper and lower hemispheres of eukaryotic cytosolic

group II chaperonins (TRiC). Clients enter the folding chambers through open lids (dashed black lines). The binding and hydrolysis of ATP induces lid closing and folding of the client within the sealed chamber of a hemisphere. Release of inorganic phosphate and ADP opens the lid, releasing the client, and resets the chamber for additional rounds of folding (not shown).

[Part (a) Data from Z. Xu, A. L. Horwich, and P. B. Siegler, 1997, *Nature* **388**:741–750, PDB ID 1aon. Part (c) Data from movie S1, from M. Jin et al., 2019, *Proc. Nat'l. Acad. Sci. USA* **116**(39):19513–19522.]

Figure 3-20b illustrates the GroEL/GroES cycle of protein folding. A partially folded or misfolded polypeptide of less than 60 kDa in mass is captured by hydrophobic residues near the entrance of the GroEL chamber and enters one of the folding chambers (upper chamber in Figure 3-20b). The second chamber is blocked by a GroES lid. Each of the 14 subunits of GroEL can bind ATP, hydrolyze it, and subsequently release ADP. These reactions are concerted for each set of seven subunits in a single ring and lead to major conformational changes. The binding of ATP causes the GroES lid to seal the chamber and alters the environment of the chamber in which polypeptide folding takes place. The polypeptide remains encased in the chamber capped by the lid. There it can undergo folding until ATP hydrolysis in that chamber, which is the slowest, rate-limiting step in the cycle, induces ATP and a different GroES to bind to the other ring. This then causes the GroES lid and ADP bound to the peptide-containing ring to be released, opening the chamber and permitting the folded protein to diffuse out. If the polypeptide is folded properly, it can proceed to function in the cell.

If it remains partially folded or misfolded, it can rebind to an unoccupied GroEL and the cycle can be repeated.

There is a reciprocal relationship between the two rings in one GroEL complex. The capping of one chamber by GroES to permit substrate folding to proceed in that chamber is accompanied by the release of substrate polypeptide from the other chamber (simultaneous binding, folding, and release from the second chamber is not illustrated in Figure 3-20b). There is a striking similarity between the capped-barrel design of GroEL/GroES, in which proteins are sequestered for folding, and the structure of the 26S proteasome that participates in protein degradation (discussed in Section 3.4). In addition, a group of proteins that are part of the AAA^+ family of ATPases are composed of hexameric rings with a central pore into which substrates can enter for folding or unfolding or in some cases proteolysis; examples of these will be discussed in Section 3.4 and in Chapter 13.

In the Group II chaperonins present in the cytosol of eukaryotes (e.g., yeast TRiC in Figure 3-20c), the consequences of ATP binding and hydrolysis differ from those in GroEL/GroES. For TriC, ATP binding and hydrolysis in the presence of bound client protein leads to closing of the lid and folding of the client in the sequestered environment within the folding chamber. Release of the inorganic phosphate opens the lid and releases the substrate and ADP release resets the TriC chamber so that it can bind another client molecule.

Abnormally Folded Proteins Can Form Amyloids That Are Implicated in Diseases

After it is synthesized, a protein may fold into an alternative, abnormal three-dimensional structure as the result of mutations, inappropriate covalent modifications, or chemical (e.g., pH) or physical (e.g., heat) alterations in its environment. A misfolded protein may not function normally and may be marked for destruction through proteolytic degradation, as described later in this chapter. However, when degradation is incomplete or fails to keep pace with the production of misfolded protein, the misfolded protein or its proteolytic fragments can accumulate either inside or outside of cells in aggregates, or *plaques*. Such plaques may be present in various organs, including joints between bones, the liver, and the brain. Even those proteins or protein fragments that are normally highly resistant to aggregation, as is the case for intrinsically disordered proteins or protein fragments, will form aggregates if their concentrations are sufficiently elevated or when there are changes in environmental conditions.

As noted above, such aggregates can either be amorphous or have a well-organized structure, which most commonly is the *amyloid state*. Strikingly, many diverse proteins can each aggregate into amyloid fibrils that have a common structure, called a *cross-β sheet* (Figure 3-21a). Short segments, generally 6–12 residues long, in the unfolded

or misfolded proteins hydrogen-bond to each other, forming a long array, or filament, of β sheets. In these arrays, each β strand is nearly perpendicular to the long axis of the filament, and two long, nearly flat β sheets pack closely together and twist around each other to form protofilaments, which then assemble together into thicker filaments, called *amyloid fibrils*. Within each protofilament the β strands can be either parallel or antiparallel (see Figure 3-5). Although some proteins form amyloid fibrils in their native, functional states, most amyloids are considered to be consequences of protein misfolding.

FIGURE 3-21 Misfolded proteins can form ordered amyloid aggregates based on a cross-β sheet structure. (a) In unfolded segments of proteins and polypeptides, exposed segments 6–12 residues long (short, flat arrows) can assemble into β sheets (see also Figure 3-5) in which each β strand is oriented nearly perpendicularly to the long axis (vertical in this figure) of the resultant amyloid protofilament and hydrogen-bonded (light shading) to the strands above and below. Two long, nearly flat sheets pack closely together and twist around each other to form amyloid protofilaments, which then assemble together into thicker filaments called *amyloid fibrils* (b). Amyloid fibrils can be composed of varying numbers of protofilaments. A model of a fibril containing four protofilaments fit into the electron density (blue) of acid-denatured insulin fibrils (*left*) and a cryoelectron microscopic image of fibrils containing two-protofilaments from fragments of transthyretin with an NMR-based model (yellow). Fibrils can aggregate into macroscopic plaques and tangles that are deposited in tissues and, when stained, are large enough to be visible using light microscopy. (c) Microscopic view of a section of human brain tissue from a patient with Alzheimer's disease showing multiple amyloid plaques and fibrillary tangles.

Association with Protein Misfolding Diseases," *Nat. Rev. Mol. Cell Biol*. **15**(6):384–396, Fig. 3a; permission conveyed through Copyright Clearance Center, Inc.]

Amyloids were first recognized in protein aggregates that are deposited in tissues. They are resistant to enzymatic degradation and are associated with dozens of diseases, called *amyloidoses*. These diseases include neurodegenerative diseases such as Alzheimer's disease and Parkinson's disease in humans and transmissible spongiform encephalopathy ("mad cow" disease) in cows and sheep. Each of these diseases is characterized by the presence of filamentous plaques in a deteriorating brain (Figure 3-21b). Amyloidoses most commonly occur with aging; however, mutations in the genes encoding the aggregating protein can result in early amyloid formation and disease onset. The amyloid fibrils composing the plaques derive from abundant natural proteins. For example, fragments of the amyloid precursor protein, which is embedded in the plasma membrane, form the plaque found in the brains of patients with Alzheimer's disease; and prion protein, an infectious protein, forms fibrils in prion diseases. In Alzheimer's disease, a hyperphosphorylated form of the protein tau, normally a microtubule-binding protein (see Chapter 18), forms twisted fibers called *tangles*. These amyloids, either as relatively short, water-soluble protofilaments or as long, insoluble fibrils, are thought to be toxic and to contribute directly to the pathology of amyloidoses. ■

KEY CONCEPTS OF SECTION 3.2

Protein Folding

- The primary structure (amino acid sequence) of a protein determines its three-dimensional structure, which determines its function. In short, function derives from structure; structure derives from sequence.
- Because protein function derives from protein structure, newly synthesized proteins must fold into the correct shape to function properly.
- The planar structure of the peptide bond limits the number of conformations a polypeptide can have (see Figure 3-16). Peptidyl-proline isomerases facilitate formation of the proper conformation of proline-containing peptide bonds.
- The amino acid sequence of a protein dictates its folding into a specific three-dimensional conformation, the native state. Proteins will unfold, or denature, if treated under conditions that disrupt the noncovalent interactions stabilizing their three-dimensional structures.
- Two broad classes of non-native conformations are seen in misfolded or denatured proteins: (1) monomeric unfolded or denatured structures and (2) aggregates, which can either be amorphous or have a well-organized structure.
- Protein folding in vivo occurs with assistance from ATP-dependent chaperones. Chaperones can influence proteins in several ways, including by preventing misfolding and aggregation, facilitating proper folding, and maintaining an appropriate, stable structure required for subsequent protein activity (see Figure 3-19).
- There are two broad classes of chaperones: (1) molecular chaperones, which bind to a short segment of a substrate protein, and (2) chaperonins, which form folding chambers in which all or part of an unfolded protein can be sequestered, giving it time and an appropriate environment to fold properly. Cycles of ATP binding and hydrolysis, followed by exchange of the ADP produced with a new ATP molecule, play key roles in the mechanisms of protein folding by chaperones.
- Many misfolded or denatured proteins can form well-organized aggregates, called *amyloid fibrils*, made by short stretches of polypeptide that form a long array of β sheets nearly perpendicular to the fibril axis, called a *cross-β structure*. Formation of amyloid fibrils that are resistant to degradation by diverse enzymes is associated with dozens of diseases called *amyloidoses*. Examples include the neurodegenerative diseases Alzheimer's disease and Parkinson's disease.

3.3 Protein Binding and Enzyme Catalysis

Proteins perform an extraordinarily diverse array of activities both inside and outside cells, yet most of these diverse functions are based on the ability of proteins to engage in a common activity: binding. Proteins bind to one another, to other macromolecules, to small molecules, and to ions. In this section, we describe some key features of protein binding and then turn to look at one group of proteins, enzymes, in greater detail. The activities of the other functional classes of proteins (structure, movement, transport, and signaling) will be described in later chapters.

Specific Binding of Ligands Underlies the Functions of Most Proteins

The molecule to which a protein binds is called its **ligand**. In some cases, ligand binding causes a change in the shape of a protein. Such conformational changes are integral to the mechanism of action of many proteins and are important in regulating protein activity.

Two properties of a protein characterize how it binds ligands. **Specificity** refers to the ability of a protein to bind one molecule or a very small group of molecules in preference to all other molecules. *Affinity* refers to the tightness or strength of binding, usually

expressed as the dissociation constant (K_d). The K_d for a protein-ligand complex, which is the inverse of the equilibrium constant K_{eq} for the binding reaction, is the most common quantitative measure of affinity (see Chapter 2). The stronger the interaction between a protein and ligand, the lower the value of K_d. Both the specificity and the affinity of a protein for a ligand depend on the structure of the *ligand-binding site*. For high-affinity and highly specific interactions to take place, the shape and chemical properties of the binding site must be complementary to those of the ligand molecule, a property termed **molecular complementarity**. As we saw in Chapter 2, molecular complementarity allows molecules to form multiple noncovalent interactions at close range and thus stick together.

One of the best-studied examples of protein-ligand binding, involving high affinity and exquisite specificity, is the binding of antibodies to antigens. *Antibodies* are proteins that circulate in the blood and are made by the immune system in response to *antigens*, which are usually macromolecules present in infectious agents (e.g., a bacterium or a virus) or other foreign substances (e.g., proteins or polysaccharides in pollens). Different antibodies are generated in response to different antigens, and these antibodies have the remarkable characteristic of binding specifically to ("recognizing") the part of the antigen, called an *epitope*, that initially induced the production of the antibody, and not to other molecules. Antibodies act as specific sensors for antigens, forming antibody-antigen

complexes that initiate a cascade of protective reactions in cells of the immune system. Chapter 24 discusses antibodies, how they are generated, and their roles in the immune system, and later in this chapter we will discuss techniques for studying proteins that exploit antibodies. Here we briefly introduce the structure of antibodies and their binding to epitopes.

Antibodies are Y-shaped molecules, often formed from two identical longer, or *heavy*, chains and two identical shorter, or *light*, chains. In IgG antibodies (also called *immunoglobulins*, shown in Figure 3-22a and b), there are four globular domains in each heavy chain and two in each light chain, all of which are called *immunoglobulin (Ig) domains*. Each of the two branching arms of an IgG antibody contains a single light chain linked to a heavy chain by a disulfide bond, and two disulfide bonds covalently link the two heavy chains together. Near the end of each arm are six highly variable loops, called *complementarity-determining regions (CDRs)*, which form the antigen-binding sites. The sequences of the six loops are highly variable among antibodies, generating unique complementary ligand-binding sites that make them specific for different epitopes (Figure 3-22c). The intimate contact between antibody and epitope surfaces, stabilized by numerous noncovalent interactions, is responsible for the extremely precise binding specificity exhibited by an antibody.

FIGURE 3-22 Protein-ligand binding of antibodies. (a) Hybrid (surface and ribbon) model of an antibody. Every antibody molecule of the immunoglobulin G (IgG) class consists of two identical heavy chains (medium and dark blue) and two identical light chains (light blue) covalently linked by disulfide bonds (yellow). The complementarity-determining regions (CDRs) that define the antigen-binding sites are represented by red shading. (b) The cartoon shows the overall structure containing the two heavy (longer) and two light (shorter) chains, with yellow bars representing disulfide bonds. (c) The hand-in-glove fit between an antibody and the site to which it binds (epitope) on its target antigen — in this case, chicken egg-white lysozyme. The antibody contacts the antigen with residues from its CDRs.

The specificity of antibodies is so precise that they can distinguish between the cells of individual members of a species and in some cases between proteins that differ by only a single amino acid, or even between proteins with identical sequences that differ only in their post-translational modifications. Because of their specificity and the ease with which they can be produced (see Chapter 24),

antibodies are highly useful reagents used in many of the experiments discussed in subsequent chapters.

We will see many examples of protein-ligand binding throughout this book, including binding of hormones to receptors (see Chapter 15), binding of regulatory molecules to DNA (see Chapter 8), and binding of cell-adhesion molecules to extracellular matrices (see Chapter 20), to name just a few. Here we focus on how the binding of one class of proteins, enzymes, to their ligands results in the catalysis of the chemical reactions essential for the survival and function of cells.

Enzymes Are Highly Efficient and Specific Catalysts

Proteins that catalyze chemical reactions — the making and breaking of covalent bonds — are called **enzymes**, and the ligands of enzymes are called **substrates**. Enzymes make up a large and very important functional class of proteins — indeed, almost every chemical reaction in the cell is catalyzed by a specific catalyst, usually an enzyme. Another form of catalytic macromolecule in cells is made from RNA. These RNAs are called **ribozymes** (see Chapter 5).

Thousands of different types of enzymes, each of which catalyzes a single chemical reaction or a set of closely related reactions, have

been identified. Certain enzymes are found in the majority of cells because they catalyze the synthesis of common cellular products (e.g., proteins, nucleic acids, and phospholipids) or take part in harvesting energy from nutrients (e.g., by the conversion of glucose and oxygen into carbon dioxide and water during cellular respiration; see Chapter 12). Other enzymes are present only in a particular type of cell because they catalyze chemical reactions unique to that cell type (e.g., the enzymes in neurons that convert tyrosine into dopamine, a neurotransmitter). A particularly important class of enzymes in cell biology are those used to communicate information about the internal and external state of the cell (signaling enzymes). This group of enzymes includes kinases that attach phosphate groups to proteins and lipids and phosphatases that remove them, as well as large and small GTP-hydrolyzing proteins. Other critical enzymes in cell biology function in controlling gene expression by causing structural changes in the nuclear DNA. These enzymes include topoisomerases, polymerases, and chromatin-modifying enzymes that can acetylate, de-acetylate, or methylate DNA-binding histones. Although most enzymes are located within cells, some are secreted and function at extracellular sites, such as the blood (clotting enzymes), the digestive tract (hydrolyases that digest dietary macromolecules), or even outside the organism (e.g., toxic enzymes in the venom of poisonous snakes).

Like all *catalysts* (see Chapter 2), enzymes increase the rate of a reaction, but they do not affect the extent of a reaction, which is determined by the change in free energy (ΔG) between reactants and products, and they are not themselves permanently changed as a consequence of the reaction they catalyze. Enzymes increase the reaction rate by lowering the energy of the *transition state*, and therefore the *activation energy* required to reach it (Figure 3-23). In the test tube, catalysts such as charcoal and platinum facilitate reactions, but usually only at high temperatures or pressures, at extremes of high or low pH, or in organic solvents. Within cells, however, enzymes must function effectively in an aqueous environment at 37 °C and 1 atmosphere of pressure and at physiological pH values, usually 6.5–7.5 but sometimes lower. Enzymes exhibit immense catalytic power, in some cases accelerating the rates of reactions to $10^6 - 10^{12}$ times those of the corresponding uncatalyzed reactions under otherwise similar conditions.

FIGURE 3-23 Effect of an enzyme on the activation energy of a chemical reaction. This hypothetical reaction pathway depicts the changes in free energy, *G*, as a reaction proceeds. A reaction will take place spontaneously only if the total *G* of the products is less than that of the reactants (negative ΔG). However, all chemical reactions proceed through one or more high-energy transition states, and the rate of a reaction is inversely proportional to the activation energy ($\Delta G^{\ddagger}$), which is the difference in free energy between the reactants and the transition state (highest point along the pathway). Enzymes and other catalysts accelerate the rate of a reaction by reducing the free energy of the transition state and thus $\Delta G^{\ddagger}$.

An Enzyme's Active Site Binds Substrates and Carries Out Catalysis

Certain amino acids of an enzyme are particularly important in determining its specificity and catalytic power. In the native

conformation of an enzyme, critically important amino acids (which usually come from different parts of the linear sequence of the polypeptide) are brought into proximity, forming a cleft in the enzyme surface called the **active site** (Figure 3-24). An active site usually makes up only a small part of the total protein; the remaining part is involved in the folding of the polypeptide, regulation of the active site, and interactions with other molecules.

FIGURE 3-24 Active site of the enzyme trypsin. (a) An enzyme's active site (outlined by dashed line) is composed of a substrate-binding site (blue), which binds specifically to a substrate, and a catalytic site (purple), which carries out catalysis. (b) A surface-and-ribbon representation of a portion of the serine protease trypsin. Clearly visible are the active-site cleft containing the catalytic site (purple, includes the key catalytic triad of Ser-195, Asp-102, and His-57, see also Figure 3-28) and a portion of the substrate-binding site called the *side-chain-specificity binding pocket* (blue).

[Data from B. Sandler, M. Murakami, and J. Clardy, 1998, *J. Am. Chem. Soc.* **120**:595–596, PDB ID 1aq7.]

An active site consists of two functionally important regions: the *substrate-binding site,* which recognizes and binds the substrate or substrates, and the *catalytic site,* which carries out the chemical reaction once the substrate has bound. The catalytic groups in the catalytic site are amino acid side chains and backbone carboxyl and amino groups. In some enzymes, the catalytic and substrate-binding sites overlap; in others, the two regions are spatially distinct.

The substrate-binding site is responsible for the remarkable specificity of enzymes. An alteration in the structure of an enzyme's substrate by only one or a few atoms, or a subtle change in the geometry (e.g., stereochemistry) of the substrate, can result in a variant molecule that is no longer a substrate of the enzyme. As with the specificity of antibodies for antigens described above, the specificity of enzymes for substrates is a consequence of the precise molecular complementarity between an enzyme's substrate-binding site and the substrate. Usually only one or a few substrates can fit precisely into a binding site so that catalysis takes place.

The idea that substrates might bind to enzymes in the manner of a key fitting into a lock was first suggested by Emil Fischer in 1894. In the late 1940s Linus Pauling proposed that enzymes could facilitate catalysis by binding more tightly to the transition state of the

reaction than to the substrate itself, and thus lower the activation energy $\Delta G^{\ddagger}$ by stabilizing the transition state (see Figure 3-23). Daniel Koshland in 1958 proposed a variation of the lock-and-key model, called *induced fit*. The induced fit model posits that the substrate-binding site is not rigid, as a lock is, but flexible, and that substrate binding induces the enzyme to change shape and consequently bind most strongly to the transition state, thereby optimizing catalysis. As early as 1913, Leonor Michaelis and Maud Leonora Menten provided crucial evidence supporting the enzyme-substrate-binding hypothesis. They showed that the rate of an enzymatic reaction was proportional to the substrate concentration at low substrate concentrations, but that as substrate concentrations increased, the rate reached a plateau, or **V_{max} (maximal velocity)**, and became independent of the substrate concentration. The value of V_{max} was directly proportional to the amount of enzyme present in the reaction mixture (Figure 3-25).

FIGURE 3-25 K_m and V_{max} for an enzyme-catalyzed reaction. K_m and V_{max} are determined by analyzing how the initial reaction rate depends on substrate concentration. The shape of these hypothetical kinetic curves is characteristic of a simple enzyme-catalyzed reaction in which one substrate (S) is converted into product (P). The initial reaction velocity is measured immediately after addition of enzyme to substrate, before the substrate concentration changes appreciably. (a) Plots of initial reaction velocity at two different concentrations of enzyme [E] as a function of substrate concentration [S]. The [S] that yields a half-maximal reaction rate is the Michaelis constant K_m, a measure of the affinity of E for turning S into P. Quadrupling the enzyme concentration causes

a proportional increase in the reaction rate, so the maximal velocity $V_{\max}$ is quadrupled; K_{m}, however, is unaltered. (b) Plots of initial reaction velocity versus substrate concentration with a substrate S for which the enzyme has a high affinity and with a substrate S' for which the enzyme has a lower affinity. Note that $V_{\max}$ is the same with both substrates because [E] is the same, but that K_{m} is higher for S', the low-affinity substrate.

Michaelis and Menten deduced that these characteristics were due to the binding of substrate molecules (S) to a fixed and limited number of sites on the enzymes (E), and they called the bound species the *enzyme-substrate (ES) complex*. At high concentrations of substrate, all the binding sites on the enzymes have substrate bound, and the substrate-binding sites are said to be *saturated* with substrate — no additional binding to active sites is possible, and the maximal velocity of the reaction is achieved. Michaelis and Menten proposed that the ES complex is in equilibrium with the unbound enzyme and substrate and is an intermediate step followed by the conversion of substrate to product (P) (Figure 3-26):

$$\mathrm{E} + \mathrm{S} \rightleftharpoons \mathrm{ES} \rightarrow \mathrm{E} + \mathrm{P}$$

Lodish et al., *Molecular Cell Bi*

FIGURE 3-26 Schematic model of an enzyme's reaction mechanism. Enzyme kinetics suggest that an enzyme (E) binds substrate molecules (S) at a fixed and limited number of sites — the enzyme's active sites. The bound species is known as an *enzyme-substrate (ES) complex*. The ES complex is in equilibrium with the unbound enzyme and substrate (double arrows) and is an intermediate step in the conversion of substrate to products (P).

In principle, all enzymatic reactions are reversible as can be seen in the glycolytic pathway (see Figure 12-3). However, because of the conditions under which they proceed or the type of chemical reaction catalyzed, many other enzymatic reactions are, in practice, virtually irreversible. The rate V_0 of formation of product at a particular substrate concentration [S] is given by what is now called the *Michaelis–Menten equation*:

$$V_0 = V_{\max} \frac{[\mathrm{S}]}{[\mathrm{S}] + K_{\mathrm{m}}} \tag{3-1}$$

where the **Michaelis constant, K_{m},** a measure of the affinity of an enzyme for its substrate, is the substrate concentration that yields a half-maximal reaction rate (i.e., $\frac{1}{2}V_{\max}$ in Figure 3-25). The K_{m} is somewhat similar in nature, but not identical, to the dissociation constant, K_{d} (see Section 2.3). The smaller the value of K_{m}, the more effective the enzyme is at making product from dilute solutions of substrate, and the lower the substrate concentration needed to reach half-maximal velocity. The smaller the K_{d}, the lower the ligand concentration needed to reach 50 percent of binding. The concentrations of the various small molecules in a cell vary widely, as do the K_{m} values for the different enzymes that act on them. A good rule of thumb is that the intracellular concentration of a substrate is often approximately the same as, or

somewhat greater than, the K_m value of the enzyme to which it binds.

The rates of reaction at substrate saturation vary enormously among enzymes. The maximum number of substrate molecules converted to product at a single enzyme active site per second, called the *turnover number*, can be less than one for very slow enzymes. The turnover number for carbonic anhydrase, one of the fastest enzymes, is 6×10^5 molecules per second.

Many enzymes catalyze the conversion of substrates to products by dividing the process into multiple, discrete chemical reactions, in which the product of one reaction is the substrate for the subsequent reaction. These sequential reactions generate multiple, distinct enzyme-substrate complexes (ES, ES', ES'', etc.) prior to the final release of the products:

$$\mathrm{E} + \mathrm{S} \rightleftharpoons \mathrm{ES} \rightleftharpoons \mathrm{ES}' \rightleftharpoons \mathrm{ES}'' \rightleftharpoons \ldots \mathrm{E} + \mathrm{P}$$

The energy profiles for such multistep reactions contain multiple hills and valleys (Figure 3-27). Methods have been developed to trap the intermediates in such reactions to learn more about the details of how enzymes catalyze reactions.

FIGURE 3-27 Free-energy reaction profiles of uncatalyzed and multistep enzyme-catalyzed reactions. (a) The free-energy reaction profile of a hypothetical simple uncatalyzed reaction converting substrate (S) to product (P) via a single high-energy transition state. (b) Many enzymes catalyze such reactions by dividing the process into multiple discrete steps, in this case, the initial formation of an ES complex followed by conversion via a single transition state ($EX^{\ddagger}$) to the free enzyme (E) and P. The activation energy for each of these steps is significantly less than the activation energy for the uncatalyzed reaction; thus the enzyme dramatically enhances the reaction rate.

Serine Proteases Demonstrate How an Enzyme's Active Site Works

Serine proteases, a large family of protein-cleaving, or proteolytic, enzymes, are used throughout the biological world — to digest meals (the pancreatic enzymes trypsin, chymotrypsin, and elastase), to control blood clotting (the enzyme thrombin), even to help silk moths chew their way out of their cocoons (cocoonase). This class of enzymes usefully illustrates how an enzyme's substrate-binding site

and catalytic site cooperate in multistep reactions to convert substrate to product. Here we consider how trypsin and its two evolutionarily closely related pancreatic proteases, chymotrypsin and elastase, catalyze cleavage of a peptide bond in a polypeptide substrate:

where X is the part of the protein on the N-terminal side of the peptide bond to be cleaved and Y is the part of the protein on the C-terminal side. We first consider how serine proteases bind specifically to their substrates and then show in detail how catalysis takes place.

Figure 3-28a shows how a substrate polypeptide binds to the substrate-binding site in the active site of trypsin. There are two key binding interactions. First, the substrate (black polypeptide backbone) and enzyme (blue polypeptide backbone) form hydrogen bonds that resemble those of a β sheet. Second, a key side chain of the substrate that determines which peptide in the substrate is to be cleaved extends into the enzyme's *side-chain-specificity binding pocket*, at the bottom of which resides the negatively charged side chain of trypsin's Asp-189. Trypsin has a marked preference for hydrolyzing

substrates at the carboxyl (C=O) side of an amino acid with a long, positively charged side chain (arginine or lysine) because the side chain is stabilized in the enzyme's side-chain-specificity binding pocket by the negative Asp-189.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 3-28 Substrate binding in the active site of trypsin-like serine proteases. (a) The active site of trypsin (purple and blue molecule) with a bound substrate (black molecule). The substrate forms a two-stranded β sheet with trypsin's substrate-binding site, and the side chain of an arginine (R_3) in the substrate is bound in the side-chain-specificity binding pocket of the binding site. Its positively charged guanidinium group is stabilized by the

negative charge on the side chain of the enzyme's Asp-189. This binding aligns the peptide bond of the arginine appropriately for hydrolysis catalyzed by the enzyme's active-site catalytic triad (side chains of Ser-195, His-57, and Asp-102). (b) The amino acids lining the side-chain-specificity binding pocket determine its shape and charge and thus its binding properties. Trypsin accommodates the positively charged side chains of arginine and lysine; chymotrypsin, large, hydrophobic side chains such as phenylalanine; and elastase, small side chains such as glycine and alanine.

[Panel (a) data from J. J. Perona and C. S. Craik, 1997, *J. Biol. Chem.* **272**:29987–29990.]

Slight differences in the structures of otherwise similar binding pockets help explain the differing substrate specificities of two serine proteases related to trypsin: chymotrypsin prefers large aromatic groups (as in Phe, Tyr, Trp), and elastase prefers the small side chains of Gly and Ala (Figure 3-28b). The uncharged Ser-189 in chymotrypsin allows large, uncharged, hydrophobic side chains to bind stably in the binding pocket. The specificity of elastase is influenced by the replacement of glycines in the sides of the binding pocket in trypsin with the branched aliphatic side chains of valines (Val-216 and Val-190), which obstruct the binding pocket (Figure 3-28b). As a consequence, large side chains in substrates are prevented from fitting into the binding pocket of elastase, whereas substrates with the short alanine or glycine side chains at this position can bind well and be subject to subsequent cleavage.

In the catalytic site, all three enzymes use the hydroxyl group on the side chain of a serine at position 195 to catalyze the hydrolysis of

peptide bonds in substrate proteins. A catalytic triad formed by the three side chains of Ser-195, His-57, and Asp-102 participates in what is essentially a two-step hydrolysis reaction. Polypeptide substrate binding to the binding site on the enzyme aligns the peptide bond to be cleaved with the enzyme's active-site catalytic triad. Figure 3-29 shows how the catalytic triad cooperates in breaking the peptide bond, with Asp-102 and His-57 supporting the attack of the hydroxyl oxygen of Ser-195 on the carbonyl carbon in the substrate. This attack initially forms an unstable transition state with four groups attached to the carbon (tetrahedral intermediate). Breaking of the C—N peptide bond then releases one part of the substrate protein (NH_3—Y), while the other part remains covalently attached to the enzyme via an ester bond to the serine's oxygen, forming a relatively stable acyl enzyme intermediate. The subsequent replacement of this oxygen with one from water, in a reaction involving another unstable tetrahedral intermediate, leads to release of the final product (X—COOH). The tetrahedral intermediate transition states are partially stabilized by hydrogen bonding with the enzyme's backbone amino groups in what is called the *oxyanion hole*. The large family of serine proteases and related enzymes, all of which have an active-site serine, illustrates how an efficient reaction mechanism is used over and over by distinct enzymes to catalyze similar reactions.

FIGURE 3-29 Mechanism of serine protease–mediated hydrolysis of peptide bonds. The catalytic triad of Ser-195, His-57, and Asp-102 in the active sites of serine proteases employs a multistep mechanism to hydrolyze peptide bonds in target proteins. (a) After a polypeptide substrate binds to the active site (see Figure 3-27), forming an ES complex, the hydroxyl oxygen of Ser-195 attacks the carbonyl carbon of the substrate's targeted peptide bond (yellow). Movements of electrons are indicated by arrows. (b) This attack results in the formation of a transition state called the *tetrahedral intermediate*, in which the negative charge on the substrate's oxygen is stabilized by hydrogen bonds formed with the enzyme's *oxyanion hole*. (c) Additional electron movements result in the breaking of the peptide bond, release of one of the reaction products (NH_2—Y), and formation of the acyl enzyme (ES′ complex). (d) An oxygen from a solvent water molecule then attacks the carbonyl carbon of the acyl enzyme. (e) This attack results in the formation of a second tetrahedral intermediate. (f) Additional electron movements result in the breaking of the Ser-195–substrate bond (formation of the EP complex) and release of the final reaction product (X—COOH). The side chain of His-57, which is held in the proper orientation by hydrogen bonding to the side chain of Asp-102, facilitates catalysis by withdrawing and donating protons throughout the reaction (*inset*). If the pH is too low and the side chain of His-57 is protonated, it cannot participate in catalysis and the enzyme is inactive.

The serine protease mechanism illustrates several key features of enzymatic catalysis. First, enzyme catalytic sites have evolved to stabilize the binding of a transition state, thus lowering the activation energy and accelerating the overall reaction. Second, multiple side chains, together with the polypeptide backbone, carefully organized in three dimensions, work together to chemically transform substrate into product, often by multistep reactions.

Third, acid-base catalysis mediated by one or more amino acid side chains is often used by enzymes, as when the imidazole group of His-57 in serine proteases acts as a base to remove the hydrogen from Ser-195's hydroxyl group. As a consequence, only a particular ionization state (protonated or nonprotonated) of one or more amino acid side chains in the catalytic site may be compatible with catalysis, and thus the enzyme's activity may be pH dependent. For example, the imidazole of His-57 in serine proteases, whose pK_a is ~ 6.8, can help the Ser-195 hydroxyl attack the substrate only if it is not protonated. Thus the activity of the protease is low at pH < 6.8, at which the imidazole is protonated, and the shape of the pH activity profile in the pH range 4–8 matches the titration of the His-57 side chain, which is governed by the Henderson-Hasselbalch equation, with an inflection near pH 6.8 (see chymotrypsin data in Figure 3-30 and see Chapter 2). The activity drops at higher pH values, generating a bell-shaped activity curve, because the proper folding of the protein is disrupted when the amino group at the protein's

amino terminus (pK_a ~9) is deprotonated; the conformation near the active site changes as a consequence.

FIGURE 3-30 The pH dependence of enzyme activity. In some cases, ionizable (pH-titratable) groups in enzyme active sites or elsewhere in enzymes must be either protonated or deprotonated to permit proper substrate binding or catalysis, or to

permit the enzyme to adopt its correct conformation. Measurement of enzyme activity as a function of pH can be used to identify the pK_a's of these groups. The pancreatic serine proteases, such as chymotrypsin, exhibit maximum activity at around pH 8 because of titration of the active-site His-57 (i.e., the deprotonated imidazole side-chain of His-57, which is required for catalysis, $pK_a \sim 6.8$) and of the amino terminus of the protein (required for proper conformation, $pK_a \sim 9$). Many lysosomal hydrolases have evolved to exhibit a lower pH optimum (~ 4.5) to match the low internal pH in the lysosomes in which they function.

[Data from P. Lozano, T. De Diego, and J. L. Iborra, 1997, *Eur. J. Biochem*. **248**:80–85, and W. A. Judice et al., 2004, *Eur. J. Biochem*. **271**:1046–1053.]

The pH sensitivity of an enzyme's activity can be due to changes in the ionization of catalytic groups, groups that participate directly in substrate binding, or groups that influence the conformation of the protein. Pancreatic serine proteases evolved to function in the neutral or slightly basic conditions in the intestines; hence their pH optima are ~ 8. Proteases and other hydrolytic enzymes that function in acidic conditions must employ a different catalytic mechanism. This is the case for enzymes within the stomach (pH ~ 1), such as the protease pepsin, and for those within lysosomes (pH ~ 4.5), which play a key role in degrading macromolecules within cells (see the lysosomal hydrolase data in Figure 3-30). Indeed, lysosomal hydrolases, which degrade a wide variety of biomolecules (proteins, lipids, etc.), are relatively inactive at the pH in the cytosol (~ 7), which helps to protect a cell from self-digestion if these enzymes escape the confines of the membrane-bounded lysosome.

One key feature of enzymatic catalysis not seen in serine proteases but found in many other enzymes is a *cofactor* or *prosthetic group*. This helper group is a nonpolypeptide small molecule or ion (e.g., iron, zinc, copper, manganese) that is bound in the active site and plays an essential role in the reaction mechanism. Small organic prosthetic groups in enzymes are also called *coenzymes*. Some of these groups are chemically modified during the reaction and thus need to be replaced or regenerated after each reaction; others are not. Examples of coenzymes include NAD^+ (nicotinamide adenine dinucleotide), FAD (flavin adenine dinucleotide) (see Figure 2-33), and the heme groups that bind oxygen in hemoglobin or transfer electrons in some cytochromes (see Figure 12-17). Thus the chemical reactions catalyzed by enzymes are not restricted by the limited number of types of amino acids in polypeptide chains. Many of the vitamins [e.g., the B vitamins thiamine (B_1), riboflavin (B_2), niacin (B_3), and pyridoxine (B_6), as well as vitamin C], which cannot be synthesized in mammalian cells, function as, or are used to generate, coenzymes. That is why supplements of vitamins must be added to the liquid medium in which mammalian cells are grown in the laboratory (see Section 4.1).

Small molecules that can bind to active sites and disrupt catalytic reactions are called *enzyme inhibitors*. Such inhibitors are useful tools for studying the roles of enzymes in cells and organisms. Inhibitors that bind directly to an enzyme's binding site and thus compete directly with the normal substrate are called *competitive*

inhibitors. Noncompetitive inhibitors are those that interfere with enzyme activity in other ways — for example, by binding to some other site on the enzyme and changing its conformation. Enzyme inhibitors complement the use of genetic mutations and a technique called *RNA interference (RNAi)* for probing an enzyme's function in cells (see Chapter 6). In all three approaches, the cellular consequences of disrupting an enzyme's activity can be used to deduce the normal function of the enzyme. The same approaches can be used to study the functions of nonenzymatic macromolecules. Interpreting the results of inhibitor studies can be complicated, however, if, as is often the case, the inhibitors disrupt the normal activity of more than one protein.

Inhibition of protein activity by small molecules is the basis for the action of many drugs as well as chemical warfare agents. Aspirin inhibits enzymes called *cyclooxygenases*, whose products can cause pain. Sarin and other nerve gases react with the active serine hydroxyl groups of both serine proteases and a related enzyme, acetylcholine esterase, which is a key enzyme in regulating nerve conduction (see Chapter 23). ■

Enzymes in a Common Pathway Are Often Physically Associated with One Another

Enzymes taking part in a common metabolic process (e.g., the degradation of glucose to pyruvate during glycolysis; see Chapter 12) are generally located in the same cellular compartment, be it in the cytosol, at a membrane, or within a particular organelle. Within this compartment, products from one reaction can move by diffusion to the next enzyme in the metabolic pathway. Diffusion, however, entails random movement and can be a slow, relatively inefficient process for moving molecules between enzymes (Figure 3-31a). To overcome this impediment, cells have evolved mechanisms for bringing enzymes in a common pathway into close proximity, a process called *metabolic coupling*.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 3-31 Assembly of enzymes into efficient multienzyme complexes. In the hypothetical reaction pathways illustrated here, the initial reactants are converted into final products by the sequential action of three enzymes: A, B, and C. (a) When the enzymes are free in solution, or even constrained within the same cellular compartment, the intermediates in the reaction sequence must diffuse from one enzyme to the next, an inherently slow process. (b) Diffusion is greatly reduced or eliminated when the individual enzymes associate into multisubunit complexes, either by themselves or with the aid of a scaffold protein. (c) The closest integration of different catalytic activities occurs when the enzymes are fused at the genetic level, becoming domains in a single polypeptide chain.

In the simplest such mechanism, polypeptides with different catalytic activities cluster closely together as subunits of a multimeric enzyme or assemble on a common *scaffold* that holds them together (Figure 3-31b). This arrangement allows the product of one reaction to be channeled directly to the next enzyme in the pathway. In some cases, independent proteins have been fused together at the genetic level to create a single multidomain, multifunctional enzyme (Figure 3-31c). Metabolic coupling usually involves large multiprotein complexes, as described earlier in this chapter.

KEY CONCEPTS OF SECTION 3.3

Protein Binding and Enzyme Catalysis

- A protein's function depends on its ability to bind other molecules, known as *ligands*. For example, antibodies bind to a group of ligands known as *antigens*, and enzymes bind to reactants called *substrates* that will be converted by chemical reactions into products.
- The specificity of a protein for a particular ligand refers to the preferential binding of one or a few closely related ligands. The affinity of a protein for a particular ligand refers to the strength of binding, usually expressed as the dissociation constant K_{d}.
- Proteins are able to bind to ligands because of molecular complementarity between the ligand-binding sites and the corresponding ligands.
- Enzymes are catalytic proteins that accelerate the rates of cellular reactions by lowering the activation energy and stabilizing transition-state intermediates (see Figure 3-23).
- An enzyme's active site, which is usually only a small part of the protein, comprises two functional parts: a substrate-binding site and a catalytic site. The substrate-binding site is responsible for the exquisite specificity of enzymes owing to its molecular complementarity with the substrate.
- The initial binding of a substrate (S) to an enzyme (E) results in the formation of an enzyme-substrate complex (ES), which then undergoes one or more reactions

catalyzed by the catalytic groups in the catalytic site until the final product (P) is formed.

- From plots of reaction rate versus substrate concentration, two characteristic parameters of an enzyme can be determined: the Michaelis constant, K_{m}, a rough measure of the enzyme's affinity for converting substrate into product, and the maximal velocity, $V_{\max}$, a measure of its catalytic power (see Figure 3-25).
- The rates of enzyme-catalyzed reactions vary enormously, with turnover numbers (numbers of substrate molecules converted to product at a single active site at substrate saturation) ranging from fewer than 1 to 6×10^5 molecules per second.
- Many enzymes catalyze the conversion of substrates to products by dividing the process into multiple discrete chemical reactions that involve multiple distinct enzyme-substrate complexes (ES', ES'' etc.).
- Serine proteases hydrolyze peptide bonds in substrate proteins using as catalytic groups the side chains of Ser-195, His-57, and Asp-102. Amino acids lining the side-chain-specificity binding pocket in the binding site of serine proteases determine the residue in a substrate protein whose peptide bond will be hydrolyzed and account for differences in protease specificity (e.g., trypsin versus chymotrypsin and elastase).
- Enzymes often use acid-base catalysis mediated by one or more amino acid side chains, such as the imidazole group of His-57 in serine proteases, to catalyze reactions. The pH dependence of protonation of catalytic groups $(\mathrm{p}K_{\mathrm{a}})$ is often reflected in the pH-rate profile of the enzyme's activity.
- Nonpolypeptide small molecules or ions, called *cofactors* or *prosthetic groups*, bind to the active sites of some enzymes and play an essential role in enzymatic catalysis. Small organic prosthetic groups in enzymes are also called *coenzymes*; many vitamins, which cannot be synthesized in higher animal cells, function as or are used to generate coenzymes.
- Enzymes in a common metabolic pathway are often located within the same cellular compartments and may be further associated as domains of a monomeric protein, subunits of a multimeric protein, or components of a protein complex assembled on a common scaffold (see Figure 3-31).

3.4 Regulating Protein Function

Most processes in cells do not take place independently of one another or at a constant rate. The activities of all proteins and other biomolecules are regulated to integrate their functions for optimal performance for survival. For example, the catalytic activity of enzymes is regulated so that the amount of reaction product is just sufficient to meet the needs of the cell. As a result, the steady-state concentrations of substrates and products may vary depending on cellular conditions. Regulation of nonenzymatic proteins — the opening or closing of membrane channels or the assembly of a macromolecular complex, for example — is also essential.

In general, there are three ways to regulate protein activity. First, cells can increase or decrease the steady-state level of the protein by altering its rate of synthesis, its rate of degradation, or both. Second, cells can change the intrinsic activity, as distinct from the amount, of the protein. For example, through noncovalent and covalent interactions, cells can change the affinity of substrate binding, or the fraction of time the protein is in an active versus an inactive conformation. Third, there can be a change in the location or the concentration within the cell of the protein itself, of the target of the protein's activity (e.g., an enzyme's substrate), or of some other molecule required for the protein's activity (e.g., an enzyme's cofactor). All three types of regulation play essential roles in the lives and functions of cells. In this section, we first discuss

mechanisms for regulating the amount of a protein, then turn to noncovalent and covalent interactions that regulate protein activity.

Regulated Synthesis and Degradation of Proteins Is a Fundamental Property of Cells

The rate of synthesis of a protein is determined by the rate at which the DNA encoding the protein is converted to mRNA (transcription), the steady-state amount of the active mRNA in the cell, and the rate at which the mRNA is converted into newly synthesized protein (translation). These important processes are described in detail in Chapter 5.

The life spans of intracellular proteins vary from as short as a few minutes for mitotic cyclins, which help regulate passage through the mitotic stage of cell division (see Chapter 19), to as long as the age of an organism for proteins in the lens of the eye. Protein life span is controlled primarily by regulated protein degradation.

Protein degradation plays two especially important roles in the cell. First, it removes proteins that are potentially toxic, improperly folded or assembled, or damaged — including the products of mutated genes and proteins damaged by chemically active cell metabolites or stress such as heat shock. Despite the existence of

chaperone-mediated protein folding, some newly made proteins are rapidly degraded because they are misfolded. This degradation might be necessary due to failure of timely engagement of the necessary chaperones to guide the folding of the proteins or due to their defective assembly into complexes. Most other proteins are degraded more slowly, undergoing about 1–2 percent degradation per hour in mammalian cells. Second, the controlled destruction of otherwise normal proteins, along with controlled rates of synthesis, provides a powerful mechanism — called **proteostasis** — for maintaining proteins and their activities at appropriate levels and for making rapid adjustments in these levels in response to changing conditions.

Eukaryotic cells have several pathways for degrading proteins. One major pathway is degradation by enzymes within lysosomes. The acidic interior (pH $\sim$4.5) of these membrane-limited organelles is filled with a host of hydrolytic enzymes. Lysosomal degradation is directed primarily toward aged or defective organelles of the cell — a process called *autophagy* (see Chapter 14) — and toward extracellular proteins taken up by the cell. Lysosomes will be discussed at length in later chapters. Here we focus on another important degradation pathway: degradation of cytoplasmic proteins by proteasomes, which can account for up to 90 percent of the protein degradation in mammalian cells.

The Proteasome Is a Molecular Machine Used to Degrade Proteins

Proteasomes are very large, multisubunit, protein-degrading molecular machines that influence many different cellular functions, including the cell cycle (see Chapter 19); transcription and DNA repair (see Chapter 5); programmed cell death, or *apoptosis* (see Chapter 22); recognition of and response to infection by foreign organisms (see Chapter 24); and removal of misfolded proteins. There are three key steps in the degradation of a protein by proteasomes. First, the protein is tagged to target it for proteasomal degradation. It is possible for cells to control the tagging of any given protein and thus regulate the rate at which that protein is degraded by proteasomes. Second, the proteasome binds to the targeted protein via the tag and unfolds the protein as it is transferred into an internal chamber. Third, protein-cutting subunits of the proteasome within the chamber degrade the target protein into small peptides, which are released into the cytosol for further processing. We will now describe in detail the structure of proteasomes and the mechanisms underlying these three steps.

There are approximately 30,000 proteasomes in a typical mammalian cell. Proteasomes consist of roughly 60 protein subunits and have a mass of about 2.4×10^6 Da. Proteasomes have a cylindrical, barrel-like catalytic core (Figure 3-32a), called the *20S proteasome* (where *S* is a Svedberg unit based on the sedimentation

properties of the particle and is proportional to its size), which is approximately 14.8 nm tall and 11.3 nm in diameter. Bound to one or both ends of this core are either one or two 19S *regulatory particle (RP)* complexes that regulate the activity of the 20S catalytic core. When the core and one or two regulatory particles are combined, they are referred to collectively as the *26S complex*, even though the two-cap-containing complex is larger (30S). A 19S regulatory particle has 19 protein subunits, six of which can hydrolyze ATP (i.e., they are AAA-type ATPases) to provide the energy needed to unfold protein substrates and selectively transfer them into the inner chamber of the proteasome's catalytic core. Genetic studies in yeast have shown that cells cannot survive without functional proteasomes. In fact, proper proteasomal activity is so important that cells will expend as much as 30 percent of the energy needed to synthesize a protein to degrade it in a proteasome. Activities of individual proteasomes can be regulated by phosphorylation — for example, to coordinate proteasome activity with the cell cycle (see Chapter 19). In addition, the amount of proteasomes in a cell is regulated by complex feedback pathways to ensure that enough are present for protein degradation.

FIGURE 3-32 Ubiquitin- and proteasome-mediated proteolysis. (a) *Right:* The 26S proteasome has a cylindrical structure with a 19S regulatory particle (RP) at one or both ends of the 20S core particle. The 19 different subunits of the 19S RP (shown in multiple colors) include six AAA-ATPase subunits (Rpt1–6, red), which assemble into a heterohexameric ring; three ubiquitin (Ub) receptors (Rpn1, Rpn10, and Rpn13, yellow); and a deubiquitinase enzyme (DUB, Rpn11, green), which forms a heterodimer with its evolutionarily related counterpart Rpn8. Moreover, the 19S RP contains scaffolding and other proteins (tan). The two 19S RPs shown are facing in opposite directions relative to the plane of the page. The 20S core consists of four stacked heptameric rings ($\sim 110\ \text{Å diameter} \times 160\ \text{Å long}$), each containing either α (outer rings) or β (inner rings) subunits (blue). *Left:* Cutaway view of the 20S core, showing the inner chambers and regulated core gate. Proteolysis occurs within the central inner chamber of the core formed by the β rings. (b) Proteins are targeted for proteasomal degradation by polyubiquitinylation. Enzyme E1 is activated by the ATP-dependent attachment of a ubiquitin (Ub) molecule (step **1**) and then transfers this Ub molecule to a cysteine residue in E2 (step **2**). Ubiquitin ligase (E3) transfers the bound Ub molecule on E2 to the side-chain $-NH_2$ of a lysine residue in a target protein, forming an isopeptide bond (step **3**).

Additional Ub molecules are added to the Ub-modified target protein via isopeptide bonds to the previously added Ub by repeating steps **1** – **3**, forming a polyubiquitin chain (step **4**). The polyubiquitinylated target is recognized by Ub receptors in the proteasome's 19S RP (step **5**). It is followed by a series of coordinated steps accompanied by conformational changes in the 19S RP. The Ub groups are removed by the deubiquitinase enzyme (step **6**) as the target protein is moved into the proper position near the six protein (hexameric) ATPase. In step **7** ATP hydrolysis enables the hexameric ATPase subunits (red) to unfold the substrate (grabbing and pulling the polypeptide through its narrow central pore) and transfer the unfolded protein via the pore through the now opened core gate into the proteolysis chamber in the 20S core (step **7a**), in some cases coordinately with step **6**, and the protein is cleaved into short peptide digestion fragments (step **7b**) that are then released (step **7c**). (c) Space-filling model of ubiquitin showing in blue lysines (K) and amino terminus (M1) to which additional ubiquitins may be covalently added to form a polyubiquitin chain (additional discussion of polyubiquitin chains can be found later in this chapter.

[Part (a) Courtesy of Antje Aufderheide and Friedrich Foerster, data from P. Unverdorben et al., 2014, *Proc. Nat'l. Acad. Sci. USA* **111**(15):5544–5549, PDB ID 4cr2. Part (c) From R. Yau and M. Rape, 2016, *Nat. Cell Biol.* **18**:579–586.]

The catalytic core of the 20S proteasome comprises two inner rings of seven β subunits each that surround a ∼1.7-nm-diameter inner chamber. Each ring contains three proteolytic active sites facing toward the inner chamber. Two outer rings of seven α subunits each limit substrate access (see Figure 3-32a) via an entry pore called the *core gate*, whose opening is controlled by substrate binding to the 19S regulatory particle. Proteasomes can degrade most proteins thoroughly because the three active sites in each β subunit ring can cleave peptide bonds at hydrophobic residues, acidic residues, or basic residues. Polypeptide substrates must enter the chamber via the regulated ~1.3-nm-diameter core-gate aperture at the center of

the outer α subunit rings. The core gate is narrow and often allows entry of only unfolded proteins. In the 26S proteasome, the opening of the core gate is controlled by ATPases in the 19S RP. These ATPases are responsible for unfolding protein substrates and translocating those unfolded polypeptides into the inner chamber of the catalytic core (Figure 3-32b, *bottom right*). Once inside the inner chamber, the polypeptides are digested, yielding short peptides (2–24 residues long). These short peptide products exit the chamber and are further degraded rapidly by cytosolic peptidases; eventually they are converted to individual ("free") amino acids. One researcher has quipped that a proteasome is a "cellular chamber of doom" in which proteins suffer a "death by a thousand cuts."

Inhibitors of proteasome function have proved to be exceptionally useful in the laboratory and the clinic. Small molecules that inhibit proteasomes, such as MG132, are used to block degradation by proteasomes in the lab, thereby helping to reveal the role of the proteasome and, as we shall see below, of polyubiquitinylation in a wide variety of processes. Other small-molecule proteasome inhibitors have been used therapeutically. Because of the global importance of protein breakdown by proteasomes in cells, continuous, complete inhibition of proteasomes kills cells. However, the partial inhibition of proteasomes for short intervals is widely used as an approach to cancer chemotherapy, especially to treat multiple myeloma, a cancer involving the abnormal proliferation of cells that make

antibodies (immunoglobulins). The myeloma cells produce abnormally high levels of potentially toxic, aberrant immunoglobulin polypeptide chains, which are degraded by proteasomes. When proteasomes in these cancer cells are inhibited, the buildup of toxic, misfolded immunoglobulin polypeptides leads to cell death. In addition, to survive and grow, myeloma cells require the robust activity of a regulatory protein called *NF-κB* (see Chapter 16) as well as other *pro-survival* and *pro-proliferation* proteins. In turn, NF-κB can function fully and promote survival and proliferation only when its inhibitor, *I-κB*, is disengaged and degraded by proteasomes (see Chapter 16). Partial inhibition of proteasomal activity by a small-molecule inhibitor drug results in increased levels of I-κB and, consequently, reduced NF-κB activity (i.e., loss of its protective activity). Cancer cell proliferation slows, and the cells die by apoptosis (see Chapter 21). Thus multiple myeloma cells are more sensitive to proteasome inhibitors than normal cells. Consequently, *controlled* administration of proteasome inhibitors (e.g., bortezomib, carfilzomib, ixazomib), at levels that kill the cancer cells but not normal cells, has proved to be an effective therapy for multiple myeloma. ■

Ubiquitin Marks Cytosolic Proteins for Degradation in Proteasomes

Proteasomes must be able to distinguish between those proteins that need to be degraded because they are defective or scheduled to be removed and those that don't. Cells mark proteins that should be degraded by covalently attaching to them a linear chain of multiple copies of a 76-residue polypeptide called *ubiquitin (Ub)* that is highly conserved from yeast to humans. This *polyubiquitin tail* serves as a cellular "kiss of death," marking the protein for destruction in the proteasome. The ubiquitinylation process (see Figure 3-32b, steps **1**–**3**) involves three distinct steps:

1. Activation of *ubiquitin-activating enzyme (E1)* by the addition of a ubiquitin molecule, a reaction that requires ATP.
2. Transfer of this ubiquitin molecule to a cysteine residue in a *ubiquitin-conjugating enzyme (E2)*.
3. Formation of a covalent bond between the carboxyl group of the C-terminal glycine 76 of the ubiquitin bound to E2 and the amino group of the side chain of a lysine residue in the target protein, a reaction catalyzed by a *ubiquitin-protein ligase (E3)*. This type of bond is called an *isopeptide bond* because it covalently links a side-chain amino group, rather than the α-amino group, to the carboxyl group. Subsequent ligase reactions covalently attach a series of ubiquitin molecules to generate a polyubiquitin chain covalently attached to the target protein (step **4**). The ligase covalently attaches the C-terminal glycine of each additional ubiquitin molecule via an isopeptide bond to the side chain of lysine 48 of the previously added ubiquitin. (We will discuss ubiquitin linkages via other lysine side chains shortly.)

Generally once four or more ubiquitins are attached in a polyubiquitin chain, the 19S regulatory protein of the 26S proteasome (sometimes with the help of accessory proteins) recognizes the polyubiquitin-labeled protein using its Ub receptors (see Figure 3-32a). Using the hexameric ATPases, the regulatory protein unfolds the protein and transports it into the proteasome core for degradation. As a polyubiquitinylated substrate binds to the proteasome, is unfolded, and passed into the core of the proteasome, enzymes called *deubiquitinases (Dubs)* hydrolyze the bonds between the individual ubiquitins and between the targeted protein and ubiquitin, recycling the ubiquitins for additional rounds of protein modification (see Figure 3-32b). Analysis of the human genome sequence indicates that about 100 distinct Dubs are present, about 80 percent of which use cysteine in a catalytic triad similar to that in the serine proteases described earlier (the sulfhydryl in the cysteine side chain is used in place of the hydroxyl in the side chain of the serine). In some Dubs, zinc is a key participant in the catalytic reactions.

Specificity of Degradation

Targeting of specific proteins for proteasomal degradation is primarily achieved through the substrate specificity of E3 ligases (see Figure 3-32b, step **3**). As a testament to their importance, there are an estimated 600 or more ubiquitin ligase genes in the human genome. The many E3 ligases in mammalian cells ensure

that the wide variety of proteins to be polyubiquitinylated can be modified when necessary. Some E3 ligases are associated with chaperones that recognize unfolded or misfolded proteins; for example, the E3 ligase CHIP is a co-chaperone for Hsp70. These and other proteins (co-chaperones, escort factors, adapters) can guide E3 to dysfunctional proteins that cannot be readily refolded properly and, consequently, are essential to their delivery to proteasomes for degradation. In such cases, the chaperone-ubiquitinylation-proteasome system works in concert to achieve quality control of proteins. The proteasome-mediated quality control system also helps cells eliminate other deleterious proteins, including those that are mistranslated, not properly located within the cell, aggregated, mutated, chemically altered, or unable to assemble into their proper multipeptide quaternary structures. In addition to quality control, the ubiquitin-proteasome system can be used to regulate the activity of important cellular proteins. An example is the regulated degradation of proteins called *cyclins*, which control the cell cycle (see Chapter 19).

Other Functions of Ubiquitin and Ubiquitin-Related Molecules

There are several close relatives of ubiquitin that employ similar E1-, E2-, and E3-dependent mechanisms of activation and transfer to acceptor substrates. These ubiquitin-like modifiers include Sumo, which regulates nuclear import, and Atg8/LC3, a regulator of

autophagy (see Chapter 14). Furthermore, the attachment of ubiquitin to a target protein can be used for purposes other than to mark the protein for degradation, as we will see later in this section, and some of these functions involve polyubiquitin linkages other than those via Lys-48.

Like ubiquitinylation, deubiquitinylation is involved in processes other than proteasome-mediated protein degradation. Large-scale, mass-spectrometry-based *proteomic* methods described later in this chapter, together with sophisticated computational approaches, have suggested that Dubs, which are often bound in multiprotein complexes, are involved in an extraordinarily wide range of cell processes. These processes vary from cell division and cell cycle control (see Chapter 19) to membrane trafficking (see Chapter 14) to cell signaling pathways (see Chapters 15 and 16).

Noncovalent Binding Permits Allosteric, or Cooperative, Regulation of Proteins

In addition to regulating the amount of a protein, cells can also regulate the intrinsic activity of a protein. One of the most important mechanisms for regulating protein function is through allosteric interactions. Broadly speaking, **allostery** (from the Greek, "other shape") refers to any change in a protein's tertiary or

quaternary structure, or in both, induced by the noncovalent binding of a ligand. When a ligand binds to one site (A) in a protein and induces a conformational change that alters the activity of a different site (B), the ligand is called an *allosteric effector* of the protein, while site A is called an *allosteric-binding site*, and the protein is called an *allosteric protein*. By definition, allosteric proteins have multiple binding sites, at least one for the allosteric effector and at least one for other molecules with which the protein interacts. The allosteric change in activity can be positive or negative; that is, it can be an increase or a decrease in protein activity. Negative allostery often involves the end product of a multistep biochemical pathway binding to, and reducing the activity of, an enzyme that catalyzes an early, rate-controlling step in that pathway. In this way, excessive buildup of the product is prevented. This kind of regulation of a metabolic pathway is also called *end-product inhibition* or *feedback inhibition*. Allosteric regulation is particularly prevalent in multimeric enzymes and other proteins in which conformational changes in one subunit are transmitted to an adjacent subunit.

Cooperativity, a term that is often used synonymously with *allostery*, usually refers to the influence (positive or negative) that the binding of a ligand at one site has on the binding of another molecule of the *same* type of ligand at a different site. Hemoglobin presents a classic example of positive cooperative binding in that the binding of a single ligand, molecular oxygen (O_2), increases the affinity of

hemoglobin for the next oxygen molecule. Each of the four subunits in hemoglobin contains one heme molecule. The heme groups are the oxygen-binding components of hemoglobin. The binding of oxygen to the heme molecule in one of the four hemoglobin subunits induces a local conformational change whose effect spreads to the other subunits, lowering the K_d (increasing the affinity) for the binding of additional oxygen molecules to the remaining hemes and yielding a sigmoidal oxygen-binding curve (Figure 3-33). Because of the sigmoidal shape of the oxygen-saturation curve, it takes only a fourfold increase in oxygen concentration for the saturation of the oxygen-binding sites in hemoglobin to go from 10 to 90 percent. Conversely, if there were no cooperativity and the shape of the curve was typical of that for Michaelis–Menten (see Figure 3-25), or noncooperative, binding, it would take an 81-fold increase in oxygen concentration to accomplish the same increase in loading of its binding sites in hemoglobin. This cooperativity permits hemoglobin to take up oxygen very efficiently in the lungs, where the oxygen concentration is high, and unload it in tissues, where the concentration is low. Thus cooperativity amplifies the sensitivity of a system to changes in the concentration of its ligands, providing in many cases a selective evolutionary advantage.

EXPERIMENTAL FIGURE 3-33 Hemoglobin binds oxygen cooperatively. Each tetrameric hemoglobin molecule has four oxygen-binding sites; at saturation, all the sites are loaded with oxygen. The oxygen concentration in tissues is commonly measured as the partial pressure of oxygen (pO_2) in torr units (a standard measure of pressure equivalent to 1 mm of mercury under standard conditions). P_{50} is the pO_2 at which half the oxygen-binding sites are occupied; it is somewhat analogous to the K_m for an enzymatic reaction. The large change in the amount of oxygen bound over a small range of pO_2 values permits efficient unloading of oxygen in peripheral tissues such as muscle. The sigmoidal shape of a plot of saturation versus ligand concentration is indicative of cooperative binding, in which the binding of one oxygen molecule allosterically influences the binding of subsequent oxygen

molecules. In the absence of cooperative binding, a binding curve is a hyperbola, similar to the curves in Figure 3-25.

Noncovalent Binding of Calcium and GTP Are Widely Used as Allosteric Switches to Control Protein Activity

Unlike oxygen, which causes graded allosteric changes in the activity of hemoglobin, some other allosteric effectors act as switches, turning the activity of many different proteins on or off by binding to them noncovalently. Two important allosteric switches that we will encounter many times throughout this book, especially in the context of cell signaling pathways (see Chapters 15 and 16), are Ca^{2+} and GTP.

Ca^{2+}/Calmodulin-Mediated Switching

The concentration of Ca^{2+} that is free in the cytosol (not bound to molecules other than water) is kept very low ($\sim 10^{-7}$ M) by specialized membrane transport proteins that continually pump excess Ca^{2+} out of the cytosol (see Chapters 11 and 15). However, as we will learn in Chapters 11 and 15, the cytosolic Ca^{2+} concentration can increase tenfold to a hundredfold when Ca^{2+}-permeable channels in the cell-surface membranes open and allow extracellular Ca^{2+} to flow into the cell. This rise in cytosolic Ca^{2+} is

sensed by specialized Ca^{2+}-binding proteins, which alter cellular behavior by turning the activities of other proteins on or off. The importance of extracellular Ca^{2+} for cell activity was first documented by S. Ringer in 1883, when he discovered that isolated rat hearts suspended in an NaCl solution made with hard (Ca^{2+}-rich) London tap water contracted beautifully, whereas they beat poorly and stopped quickly if distilled (Ca^{2+}-depleted) water was used. The cytosolic Ca^{2+} concentration also can increase when Ca^{2+}-permeable channels in the endoplasmic reticulum open and allow Ca^{2+} stored in this organelle flow into the cytoplasm.

Many Ca^{2+}-binding proteins bind Ca^{2+} using the EF hand/helix-loop-helix structural motif discussed earlier (see Figure 3-7b). A well-studied EF hand protein, *calmodulin,* is found in all eukaryotic cells, where it may exist as an individual monomeric protein or as a subunit of a multimeric protein. This dumbbell-shaped molecule contains four Ca^{2+}-binding EF hands with K_ds of about 10^{-6} M. The binding of Ca^{2+} to calmodulin causes a conformational change that permits Ca^{2+}/calmodulin to bind to conserved sequences in various target proteins (Figure 3-34), thereby switching their activities on or off. Calmodulin and similar EF hand proteins thus function as *switch proteins,* acting in concert with changes in Ca^{2+} levels to modulate the activity of other proteins.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 3-34 Conformational changes induced by Ca^{2+} binding to calmodulin. Calmodulin is a widely distributed cytosolic protein that contains four Ca^{2+}-binding sites, one in each of its EF hand (helix-loop-helix) motifs (EF1–EF4; see also Figure 3-7). At cytosolic Ca^{2+} concentrations above about 5×10^{-7} M, binding of Ca^{2+} to calmodulin changes the protein's conformation from the dumbbell-shaped, Ca^{2+}-free form (a) to one in which hydrophobic side chains become more exposed to solvent. The resulting Ca^{2+}/calmodulin complex can wrap around exposed helices with specialized sequences in various target proteins (b), thereby altering their activities.

Switching Mediated by Guanine Nucleotide–Binding Proteins

Another group of intracellular switch proteins constitutes the *GTPase superfamily*. As the name suggests, these proteins are enzymes — GTPases — that can hydrolyze GTP (guanosine triphosphate) to GDP (guanosine diphosphate). They include the monomeric Ras protein (whose structure is shown in Figure 3-9, with bound GDP shown in blue) and the G_α subunit of the trimeric G proteins, both discussed at length in Chapters 15 and 16. Both Ras and G_α can bind to the plasma membrane, function in cell signaling, and play key roles in cell proliferation and differentiation. Other members of the GTPase superfamily function in protein synthesis, the transport of proteins between the nucleus and the cytoplasm, the formation of coated vesicles and their fusion with target membranes, vesicle-mediated membrane trafficking, and rearrangements of the actin cytoskeleton. Some GTPase proteins have a covalently attached lipid chain (see Figure 10-19) that mediates their binding to membranes. We examine the roles of various GTPase switch proteins in regulating intracellular signaling and other processes in several later chapters.

All the GTPase switch proteins exist in two forms, or conformations (Figure 3-35): (1) an active ("on") form with bound GTP, which can influence the activity of specific target proteins to which they bind, and (2) an inactive ("off") form with bound GDP. The switch is turned on — that is, the conformation of the protein changes from inactive to active — when a GTP molecule replaces a bound GDP in the inactive conformation. The switch is turned off when the relatively slow GTPase activity of the protein hydrolyzes bound GTP, converting it to GDP and leading the conformation to change to the inactive form. The amount of time any given GTPase switch remains in the active, GTP-bound form depends on the rate of its GTPase activity. Thus the GTPase activity acts as a timer to control this switch.

FIGURE 3-35 The GTPase switch. GTPases are enzymes that bind to GTP and hydrolyze it to GDP. When bound to GTP, the GTPase protein adopts its active, or "on," conformation and can interact with target proteins to regulate their activities. When the bound GTP is hydrolyzed to GDP by the intrinsic GTPase activity of the protein, the GTPase with GDP bound assumes an inactive, or "off," conformation. The GTPase switch can be turned back on when another protein, called a *GEF (guanine nucleotide exchange factor)*, mediates the replacement (exchange) of the bound GDP with a GTP molecule from the surrounding fluid.

GTPase-activating proteins, or GAPs, can influence the rates of GTP hydrolysis. The binding of the active form of the GTPase to its targets is a form of noncovalent regulation.

Cells contain a variety of proteins that can modulate the baseline (or intrinsic) rate of GTPase activity for any given GTPase switch and so can control how long the switch remains on. For example, GTPase-activating proteins, or GAPs, increase the rate of GTPase activity, thus reducing the time the GTPase is in the active form. Cells also have specific proteins whose function is to regulate the conversion of inactive GTPases to active ones — that is, to turn the switch on — by mediating the replacement of bound GDP with GTP (*GDP/GTP exchange*). These proteins are called *guanine nucleotide exchange factors*, or *GEFs*. GTPases with lipid anchors are also regulated by proteins called *guanine nucleotide dissociation inhibitors (GDIs)* that bind to the lipid chain and thus influence interactions with cellular membranes.

The GAPs, GEFs, and GDIs are themselves subject to regulation and, together with their GTPases, participate in complex regulatory networks that control a vast array of cellular activities. It is, therefore, not surprising that disruptions of these finely tuned regulatory networks by mutations or pathogens are associated with a wide variety of diseases. Examples of genetic diseases affecting these networks include Noonan syndrome (a developmental disorder), retinitis pigmentosa (a degenerative eye disease), and X-linked mental retardation. Examples of disruptions of these

networks by pathogens include bacterially induced food poisoning, dysenteries (inflammation of the intestines with diarrhea), Legionnaires' disease (a severe type of pneumonia that involves lung inflammation), and even the plague [also called the *Black Death*, which between 1347 and 1351 decimated the populations of China (~50 percent death rate) and Europe (~33 percent death rate)]. ■

Covalent Modification of Proteins Can Regulate their Activities

In addition to exploiting the noncovalent regulators described above, cells can use covalent modifications to regulate the intrinsic activity of a protein. Examples of such modifications, called **post-translational modifications (PTMs)**, include covalent addition of phosphate groups (phosphorylation), methyl groups (methylation), nitric oxide (nitroslyation), acetyl groups (acetylation), carbohydrate, fatty acyl or other hydrocarbon chains (lipidation), and even small proteins [e.g., ubiquitin (ubiquitinylation)]. The covalent modification can increase or decrease the activity of the modified protein by changing its surface characteristics (shape, charge, etc.), and thus its ability to bind to other molecules, its conformation, or both. The enzymes that covalently modify target proteins have been called *writers*, the proteins that recognize the modified proteins are called *readers*, and for those covalent modifications that are

reversible, the enzymes that remove the modifications are called *erasers*.

Phosphorylation and Dephosphorylation Covalently Regulate Protein Activity

One of the most common covalent mechanisms for regulating protein activity is **phosphorylation**, the reversible addition of a phosphate group from ATP to an hydroxyl group on the side chain of a serine, threonine, or tyrosine residue. Phosphorylated proteins are called *phosphoproteins*. Phosphorylation is catalyzed by enzymes called protein **kinases**, while the removal of phosphates, known as *dephosphorylation*, is catalyzed by **phosphatases**. The counteracting activities of kinases and phosphatases provide cells with a switch that can turn on or turn off the function of various proteins that are the substrates (or targets) of these enzymes (Figure 3-36). Protein kinases constitute one of the largest families of enzyme molecules; they are found in all eukaryotic cells and nearly all prokaryotic cells. Nearly 3 percent of all yeast proteins are protein kinases or phosphatases, indicating the importance of phosphorylation and dephosphorylation reactions even in these simple cells. Analysis of the human genome indicates there are approximately 500 human protein kinases composing the human *kinome* (see Figure 3-12b). For

simplicity, we will limit our discussion here to eukaryotic protein kinases.

FIGURE 3-36 Regulation of protein activity by phosphorylation and dephosphorylation. The cyclic phosphorylation and dephosphorylation of a protein is a common cellular mechanism for regulating protein activity. In this example, the target protein is active (*top*) when phosphorylated and inactive (*bottom*) when dephosphorylated; some proteins have the opposite response to phosphorylation.

Phosphorylation or dephosphorylation, writing or erasing, can influence the location of a protein within cells (e.g., its attachment to the inner surface of the plasma membrane); its structure and intrinsic (e.g., enzymatic) activity; its ability to bind to other molecules, including metabolites, DNA, or other proteins; its ability to undergo further covalent modification; or its stability (rate of

degradation). In addition, several conserved protein domains, such as the SH2 domain (see Figure 16-9), bind specifically to phosphorylated peptides (readers). Thus phosphorylation can mediate the formation of protein complexes that can generate or extinguish a wide variety of cellular activities, discussed in many subsequent chapters.

All classes of proteins — including structural proteins, scaffolds, enzymes, membrane channels, and signaling molecules — have members regulated by kinase and phosphatase modifications. Different protein kinases and phosphatases are specific for different target proteins, often recognizing different linear sequences in which the residue to be phosphorylated is embedded, and so can regulate distinct cellular pathways, as discussed in later chapters. Some kinases have many targets, so that a single kinase can serve to integrate the activities of many targets simultaneously. Frequently, the target of a kinase or phosphatase is yet another kinase or phosphatase, creating a cascade effect. There are many examples of such kinase cascades, which permit amplification of a signal and many levels of fine-tuning (see Chapters 15 and 16).

The Structure and Function of Protein Kinase A Is Typical of Many Kinases

The phosphate group transferred by a protein kinase to a protein substrate is provided by ATP whose three phosphates are designated α, β, and γ (red):

The γ-phosphate is transferred to a serine, threonine, or tyrosine of the polypeptide substrate. Specifically, the hydroxyl group that is part of the side chain of these three amino acids is replaced by a phosphoryl group:

The reaction products are ADP, H^+, and a phosphorylated protein — that is, a protein containing a phosphate ester (charges on the molecules are shown as superscripts). In this example, the amino acid sequence is a substrate for protein kinase A (PKA), a protein kinase that we will encounter a number of times throughout the book.

All protein kinases contain a *kinase domain*, an enzymatic module of around 250 residues that catalyzes the phosphate transfer reaction. Many protein kinases also contain additional protein domains or binding partners that assist in selecting the protein substrate, participate in regulating the kinase's enzymatic activity, help form multiprotein complexes with other cellular proteins (scaffolds), and localize the enzyme to particular sites in the cell.

In 1991, the first x-ray crystal structure of a catalytic kinase domain from the enzyme protein kinase A was determined. Its bilobed structure resembles a kidney bean (Figure 3-37a). The lobe containing the N-terminus of the domain is called the *N-lobe* and

that containing the C-terminus is called the *C-lobe*. A region in the C-lobe called the *activation loop* participates in the regulation of the kinase's enzymatic activity and will be discussed later. Most protein-kinase catalytic domains have similar structures and use similar mechanisms to catalyze phosphorylation of target proteins. Here we will focus on the prototypical kinase, PKA, one of the most thoroughly studied kinases.

FIGURE 3-37 The kinase domain of protein kinases: structure and substrate binding. A kinase domain comprises two globular lobes (N-lobe and C-lobe). The active site is located in a cleft between the two lobes, and an activation (A-) loop in the C-lobe contributes to the active site and projects outward [(a) and (b)]. (a) When catalytically active and in the absence of substrates, the active form of the kinase domain is in an "open" conformation that facilitates substrate binding. (b) When bound to substrates (ATP, $2\mathrm{Mg}^{2+}$, polypeptide substrate) in an enzyme substrate (ES) complex, the active site narrows to its "closed" conformation to facilitate the phosphorylation of the polypeptide substrate. The inset shows a magnified view of the ATP and two Mg^{2+} ions in the ES complex. Divalent metal ions help neutralize the negative charges on the phosphates of ATP. (c) Most protein kinases exhibit substrate specificity by binding to a specific sequence of residues (a sequence motif) on either side of the hydroxyl-containing residue to be phosphorylated. Binding pockets in the substrate-binding site (*right*) of PKA establish its specificity for the sequence R-R-X-(Ser or Thr)-hydrophobic (e.g., isoleucine, I, is shown). Negatively charged binding sites (rectangles) that recognize the side chains of Arg or Lys in the substrate and a hydrophobic pocket (round) that recognizes hydrophobic side chains in the substrate are illustrated. (d) Surface representations of protein kinase domains from four different proteins: CDK2; PKA, phosphorylase kinase (PHK); and insulin receptor kinase (IRK). Each has a distinctive, detailed structure and exhibits a distinct distribution of surface charges (positively charged are blue, negatively charged are red).

[Part (b) Substrate structures data from PDB ID 1ATP (https://www.rcsb.org/3d-view/1ATP/1). Parts (c) and (d) Data from Figures 3 and 1 from J. A. Ubersax and J. E. Ferrell, 2007, *Nat. Rev. Mol. Cell Biol.* **8**:530–541.]

The kinase active site is located in and around the cleft between the two lobes (see Figure 3-37a). The active site contains substrate-binding sites that bind and properly orient the ATP molecule (and two associated magnesium divalent cations, Mg^{2+}) within the cleft and the polypeptide substrate on the ledge of and adjacent to the cleft. This binding appropriately positions the hydroxyl group of the phospho-accepting serine, threonine, or tyrosine side chain relative to the ATP and the key catalytic residues in the kinase (Figure 3-37b). In the absence of substrates, the active site cleft is "open" (see Figure 3-37a). The binding of the substrates places the γ-phosphate of the ATP in close proximity to the hydroxyl group of the acceptor amino acid on the polypeptide substrate and, in an example of induced fit, induces a conformational change, primarily in the N-lobe, to a "closed" conformation that narrows the cleft (see Figure 3-37b) and establishes a configuration that optimizes catalysis. The active site also contains the catalytic site that facilitates in the transfer of the γ-phosphate group from the ATP to the polypeptide substrate.

Only a small subset of protein sequences, those containing the proper substrate motif, are able to bind productively to the active site and be phosphorylated. Different protein kinase enzymes differ in their substrate specificities. The substrate specificity of any kinase enzyme often depends on the amino acid sequence

immediately surrounding the acceptor residue, although specificity can also be influenced by other regions in the substrate protein. For example, PKA typically phosphorylates its substrate proteins on serine and threonine residues only if they are found within the sequence motif RRX**S**Φ or RRX**T**Φ, where X is any amino acid and Φ denotes a hydrophobic amino acid (e.g., see Figure 3-37c) and the phosphorylated residue is shown in bold.

A glimpse at the active site of PKA's kinase domain explains the molecular basis for this substrate specificity (Figure 3-37c). Three negatively charged, acidic side chains in the substrate-binding site directly bind to the two positively charged Arg (R) side chains in the substrate motif, and a hydrophobic pocket in PKA recognizes the hydrophobic amino acid side chain in the motif immediately C-terminal to the acceptor serine or threonine residue. As a consequence, only proteins with this sequence motif can bind productively to PKA and be phosphorylated. The substrate specificities of other kinases are similarly established by the molecular complementarity of their substrate-binding sites (including the distributions of charges and locations of binding pockets on their surfaces (Figure 3-37d) and the substrate polypeptides. Substrate specificity also can be influenced by other regions of both the kinase and substrate polypeptide.

In addition to the substrate-binding site, there are two stretches of amino acids in kinases called the *G-loop* and *A-loop* that are critically

important for substrate binding and catalysis. Binding of ATP-2Mg^{2+} or the protein enhances binding of the other substrate, in an example of cooperative binding, and, in addition, induces conformational changes in the enzyme, an example of induced fit. Once the ATP and polypeptide substrate are appropriately aligned in the active site (Figure 3-37b), the catalytic site mediates the rapid transfer of the γ-phosphate of ATP to the hydroxyl group of the acceptor amino acid on the protein substrate (see the protein kinase reaction, this page above) at rates 10^9-fold to 10^{11}-fold greater than that of the uncatalyzed phosphorylation reaction. The catalytic mechanism is completed with the sequential release of the phosphoprotein product with one bound Mg^{2+} followed by what in some kinases is the slowest step in the reaction pathway: the release of ADP with one bound Mg^{2+}. The slowest step in a multistep, enzyme-mediated catalysis is usually called the **rate-limiting step** because that step has the most profound influence on the overall rate of the reaction.

Protein Kinase Activity Is Often Regulated by Phosphorylation of the Kinase

If the activities of protein substrates are influenced by their phosphorylation by protein kinases, then there must be mechanisms that regulate the protein kinases themselves, and

indeed there are. Here we will consider one common mechanism employed to switch many protein kinases from an inactive state to an active state. This mechanism is the covalent attachment of a phosphate to a particular residue in the kinase's A-loop. Thus many kinases must be phosphorylated by another kinase — a type of enzymatic cascade — before they can be active and phosphorylate their own substrates. Phosphorylation of the kinase induces a change in its conformation that brings its substrate-binding and catalytic residues into the proper open orientation to permit efficient substrate binding and subsequent phosphate transfer. The G- and A-loops mentioned above have sequences that are conserved in many kinases and play particularly important roles in controlling the enzymatic activities of kinases.

The conserved sequence of the G-loop is G-X-G-X-X-G-X-V where X is any residue (the G in G-loop refers to the conserved glycine residues). Residues in this sequence interact with the β and γ phosphates of ATP for productive ATP binding and catalysis. A-loop residues regulate substrate binding and directly influence catalysis. When phosphorylated, one of the A-loop residues triggers activation; hence it is called the *activation (A) loop*. The residues in both loops must be properly oriented in the protein if substrates are to bind productively and phosphate transfer is to be catalyzed efficiently. Figure 3-38 shows that for PKA in the absence of phosphorylation of Thr-197 in the A-loop (*left*), neither the A-loop (thick red line) nor the G-loop (thick orange line) are in the proper

conformation and, as a consequence, the kinase is inactive. Phosphorylation of Thr-197 (yellow circle, *center*) induces a conformational change in the enzyme, generating an active, open, structure to which substrates can bind productively (Figure 3-38a *right* and 3-38b). While the conformations of the A-loop in the active structures of many different protein kinases are similar, the conformations of the A-loops in the inactive structures vary considerably. In subsequent chapters we will see many examples of how cells activate or inactivate protein kinases to control important cellular functions. We also will see, in addition to phosphorylation of the A-loop and conformational changes in the G-loop, there are a variety of scaffold proteins and inhibitory proteins that can bind to protein kinases and influence their activities.

FIGURE 3-38 PKA's G-loop, catalytic loop, and A-loop mediate substrate binding and catalysis after activation by A-loop phosphorylation. (a) The protein kinase domain of PKA is transformed from an inactive conformation (*left*) to the active, open conformation (*center*) by phosphorylation (yellow circle) of Thr-197 in the A-loop (thick red line). Phosphorylation results in conformational changes in both the A-loop and the G-loop (thick orange line). Subsequent substrate binding (ATP, yellow; $2\ Mg^{2+}$, brown; peptide substrate, blue) leads to formation of the active, closed conformation (*right*) in which substrate phosphorylation is catalyzed. (b) A surface-and-ribbon (green) representation of phosphorylated PKA in the

active, closed conformation with ATP (yellow) and a polypeptide substrate (blue) bound. The phosphorylated tyrosine (pT197) is yellow.

Ubiquitinylation and Deubiquitinylation Covalently Regulate Protein Activity

We have already seen how polyubiquitinylation can be used to tag proteins for degradation by proteasomes. The covalent addition of ubiquitin and ubiquitin-like proteins (of which there are more than a dozen in humans) to a target protein also can be used to regulate the activity of the target in a manner analogous to phosphorylation. In addition, deubiquitinases (Dubs) can remove ubiquitins in a manner analogous to the action of phosphatases. **Ubiquitinylation** can involve attachment of a single ubiquitin to a protein (*monoubiquitinylation*), addition of multiple single ubiquitin molecules to different sites on one target protein (***multiubiquitinylation***), or addition of a polymeric chain of ubiquitins to a protein (*polyubiquitinylation*), as we previously described for tagging target proteins for proteasomal degradation. An additional source of variation is that different amino groups in the ubiquitin molecule can be used to form an isopeptide bond with

the C-terminal Gly-76 in another ubiquitin to form a polyubiquitin chain. All seven lysine residues in ubiquitin (Lys-6, Lys-11, Lys-27, Lys-29, Lys-33, Lys-48, and Lys-63) and its N-terminal amino group (see Figure 3-32c) can participate in such linkages. These linkages are catalyzed by a variety of ubiquitin ligases, each specific for both the target to be ubiquitinylated and the lysine side chains that participate in the isopeptide linkages (Lys-63 or Lys-48, etc.) (Figure 3-39a). Because any one ubiquitin molecule has multiple lysines to which additional ubiquitins can be attached (see Figure 3-32c), polyubiquitin chains can be linear (Figure 3-39a) or branched (Figure 3-39b).

FIGURE 3-39 Determination of polyubiquitin function by the lysine used in isopeptide bonds linking ubiquitins. (a) Different ubiquitin ligases catalyze polyubiquitinylation of distinct target proteins (colored ovals) using distinct lysine side chains of ubiquitin molecules (purple) to generate the inter-ubiquitin isopeptide linkages (blue) with Gly-76 of the adjacent ubiquitin. Dotted blue arrows represent additional ubiquitins in the chain that are not shown. The lysine used for the isopeptide bonds determines the function of the

polyubiquitinylation. For example, polyubiquitins with Lys-48:Gly-76 isopeptide bonds direct the target to proteasomes for degradation. Those that use Lys-63, Lys-33, and Lys-11 influence signaling, T-lymphocyte control, and cell division, respectively. Isopeptide bonds involving ubiquitin's Lys-6, Lys-27, and Lys-29 and bonds involving its N-terminal amino group (not shown) can also be used to generate polyubiquitin chains. (b) Branched polyubiquitin chains can be generated by the covalent attachment of two ubiquitin molecules to two different amino groups on a single ubiquitin, in this case Lys_{48} and Lys_{11}.

The multiple forms of ubiquitinylation result in the generation of a wide variety of recognition surfaces that can participate in many protein-protein interactions with the hundreds of proteins (>200 in humans) that contain more than a dozen distinct ubiquitin-binding domains (UBD). In addition, any given polyubiquitin chain has the potential to bind simultaneously to more than one UBD-containing protein, leading to the formation of multiprotein complexes. Some deubiquitinases can remove an intact polyubiquitin chain from a modified protein ("anchored" chain) and thus generate a polyubiquitin chain not covalently linked to another protein ("unanchored" chain). Even these unanchored chains may serve a regulatory role.

With this great structural diversity, it is not surprising that cells use ubiquitinylation and deubiquitinylation to control many different functions.

Such functions include cellular internalization of molecules via endocytosis (see Chapter 14), repair of damaged DNA, metabolism, messenger RNA synthesis, defense against pathogens, cell division

and cell cycle progression, cell signaling pathways, trafficking of proteins within a cell, and apoptosis. The lysine used to form the inter-ubiquitin isopeptide bonds can vary depending on the cellular system that is regulated (Figure 3-39). For example, we have already seen that polyubiquination via Lys-48 is used to target proteins for proteasomal degradation, and there is evidence that polyubiquitinylation via other Lys residues (e.g., Lys-11 and Lys-33, but not Lys-63) can also target proteins to the proteasome. Polyubiquitinylation with Lys-63 linkages is used in many cellular identification and signaling systems, such as those that recognize the presence of intracellular viruses and bacteria and induce a protective immune response, as well as those that direct these pathogens to lysosomes for degradation. Lys-11-linked polyubiquitin chains regulate cell division. Lys-33-linked chains help suppress the activity of receptors on specialized white blood cells, called *T lymphocytes* (see Chapter 24) and thereby control the activity and function of those lymphocytes. Furthermore, additional post-translational modifications (phosphorylation, acetylation, etc.) of the ubiquitin molecules that are attached to target proteins can confer even greater capacity to manipulate the activity of the target protein.

Proteolytic Cleavage Irreversibly Activates or Inactivates Some Proteins

Unlike phosphorylation and ubiquitinylation, which are reversible, the activation or inactivation of protein function by proteolytic cleavage is an irreversible mechanism for regulating protein activity. For example, many polypeptide hormones, such as insulin, are synthesized as longer precursors, and prior to secretion from cells some of their peptide bonds must be hydrolyzed for them to fold properly. In some cases, a single, long precursor *prohormone* polypeptide is cleaved into several distinct active hormones. To prevent the pancreatic serine proteases from inappropriately digesting proteins before they reach the small intestine, they are synthesized as *zymogens*, inactive precursor enzymes. Cleavage of a peptide bond near the N-terminus of trypsinogen (the zymogen of trypsin) by a highly specific protease in the small intestine generates a new N-terminal residue (Ile-16) whose amino group can form an ionic bond with the carboxylic acid side chain of an internal aspartic acid. This binding causes a conformational change that opens the substrate-binding site, activating the enzyme. The active trypsin can then activate trypsinogen, chymotrypsinogen, and other zymogens. Similar but more elaborate protease cascades (with one protease activating inactive precursors of others) that can amplify an initial signal play important roles in several systems, such as the blood-clotting cascade and the complement system (see Chapter 24). The importance of carefully regulating such systems is clear — inappropriate clotting, for example, could fatally clog the circulatory system, while insufficient clotting could lead to uncontrolled bleeding.

An unusual and rare type of proteolytic processing, termed *protein self-splicing*, takes place in bacteria and some eukaryotes. This process is analogous to editing film: an internal segment of a polypeptide is removed and the ends of the polypeptide are rejoined (ligated). Unlike other forms of proteolytic processing, protein self-splicing is an autocatalytic process that proceeds by itself without the participation of other enzymes. The excised peptide appears to eliminate itself from the protein by a mechanism similar to that used in the processing of some RNA molecules (see Chapter 9). In vertebrate cells, the processing of some proteins includes self-cleavage, but the subsequent ligation step is absent. One such protein is Hedgehog, a membrane-bound signaling molecule that is critical to a number of developmental processes (see Chapter 16).

Higher Order Regulation Includes Control of Protein Location

All the regulatory mechanisms heretofore described affect a protein locally at its site of action, altering the protein's concentration or turning its activity on or off. Normal functioning of a cell, however, also requires the segregation of proteins to particular compartments, such as the mitochondria, nucleus, or lysosomes. In regard to enzymes, compartmentation not only provides an opportunity for controlling the delivery of substrate or the exit of product but also permits competing reactions to take place

simultaneously in different parts of a cell. We describe the mechanisms that cells use to direct various proteins to different compartments in Chapters 13 and 14. We now turn from the fundamental properties of proteins to the methods cell biologists use to study them.

KEY CONCEPTS OF SECTION 3.4

Regulating Protein Function

- Proteins may be regulated at the level of protein synthesis, protein degradation, or the intrinsic activity of proteins through noncovalent or covalent interactions.
- The life span of an intracellular protein is largely determined by its susceptibility to proteolytic degradation.
- Many proteins are marked for destruction with a covalently attached polyubiquitin tag assembled by ubiquitin ligases and then degraded within proteasomes, large cylindrical complexes with multiple protease active sites in their interior chambers (see Figure 3-32).
- Ubiquitinylation of proteins is reversible due to the activity of deubiquitinylating enzymes.
- In allostery, the noncovalent binding of one ligand molecule, the allosteric effector, induces a conformational change that alters a protein's activity or affinity for other ligands. The allosteric effector can be identical in structure to or different from the other ligands, whose binding it affects. The allosteric effector can be an activator or an inhibitor.
- In multimeric proteins, such as hemoglobin, that bind multiple identical ligand molecules (e.g., oxygen), the binding of one ligand molecule may increase or decrease the protein's affinity for subsequent ligand molecules. This type of allostery is known as *cooperativity* (see Figure 3-33).
- Several allosteric mechanisms act as switches, turning protein activity on and off in a reversible fashion.
- Noncovalent and covalent binding of ions and molecules to target proteins can regulate the activities of those target proteins.
- Two classes of intracellular switch proteins regulate a wide variety of cellular processes: (1) Ca^{2+}-binding proteins (e.g., calmodulin) and (2) members of the

GTPase superfamily (e.g., Ras), which cycle between active GTP-bound and inactive GDP-bound forms (see Figure 3-35). GTPases participate in complex regulatory networks that include proteins (GAP, GEF, GDI) that regulate the cycling of the GTPase between its active and inactive forms.

- The phosphorylation and dephosphorylation of hydroxyl groups on serine, threonine, or tyrosine side chains by protein kinases and phosphatases provide reversible on/off regulation of numerous proteins (see Figure 3-36).
- Most protein kinases use a common bilobed catalytic domain and a common catalytic mechanism to phosphorylate their substrate proteins.
- Ubiquitinylation is used to control a wide variety of cellular functions in addition to proteasome-mediated degradation, such as changes in the location or activity of proteins (see Figure 3-39). The specific covalent attachment of ubiquitin to proteins (mono-, multi-, and polyubiquitinylation involving a variety of linkages between the ubiquitin monomers) can vary depending on the cellular system that is regulated.
- Many types of covalent and noncovalent regulation are reversible, but some forms of regulation, such as proteolytic cleavage, are irreversible.
- Higher order regulation includes the intracellular location, or compartmentation, of proteins.

3.5 Purifying, Detecting, and Characterizing Proteins

A protein often must be purified before its structure and the mechanism of its action can be studied in detail. However, because proteins vary in size, shape, oligomerization state, charge, and water solubility, no single method can be used to isolate all proteins. To isolate one particular protein from the estimated 10,000 different proteins in a particular type of cell is a daunting task that requires methods both for separating proteins and for detecting the presence of specific proteins.

Any molecule, whether protein, carbohydrate, or nucleic acid, can be separated, or *resolved*, from other molecules on the basis of their differences in one or more physical or chemical characteristics. The larger and more numerous the differences between two proteins, the easier and more efficient their separation. As a practical matter, the more abundant a particular protein is in a biological sample, the easier it is to separate it from the other molecules in the sample. The three most widely used characteristics for separating proteins are *size*, defined as either length or mass; net electrical charge; and *affinity* for binding to specific ligands. In this section, we briefly outline several important techniques for separating proteins; these separation techniques are also useful for the separation of nucleic acids and other biomolecules. (Specialized methods for removing membrane proteins from membranes are described in Chapter 10

after the unique properties of these proteins are discussed.) We then consider the use of radioactive compounds for tracking biological activity. Finally, we consider several techniques for characterizing a protein's mass, sequence, and three-dimensional structure.

Centrifugation Can Separate Particles and Molecules That Differ in Mass or Density

The first step in a typical protein-purification scheme is centrifugation. The principle behind centrifugation is that two types of particles in suspension (cells, cell fragments, organelles, or molecules) with different masses or densities will settle to the bottom of a test tube at different rates. Remember, mass is the weight of a sample (measured in daltons or molecular weight units), whereas density is the ratio of its mass to volume (often expressed as grams per liter because of the methods used to measure density). Proteins vary greatly in mass, but not in density. Unless a protein has an attached lipid or carbohydrate, its density will not vary by more than 15 percent from $1.37\ \mathrm{g/cm^3}$, the average protein density. Heavier or denser molecules settle, or *sediment*, more quickly than lighter or less dense molecules.

A centrifuge speeds sedimentation by subjecting particles in suspension to centrifugal forces as great as 1 million times the force

of gravity, *g*, which can sediment particles as small as 10 kDa. Modern ultracentrifuges achieve these forces by reaching speeds of 150,000 revolutions per minute (rpm) or greater. However, small particles with masses of 5 kDa or less will not sediment uniformly even at such remarkably high rotation rates. The extraordinary technical achievements of modern ultracentrifuges can be appreciated by considering that they can rotate a several-pound rotor (about the size of an American football) that holds the samples in tubes at rates as high as 2500 revolutions per second!

Centrifugation is used for two basic purposes: (1) as a preparative technique to separate one type of material from others with the goal of obtaining enough of the material to perform subsequent experiments and (2) as an analytical technique to measure physical properties (e.g., molecular weight, density, shape, and equilibrium-binding constants) of macromolecules. The sedimentation constant, *s*, of a protein is a measure of its sedimentation rate. The sedimentation constant is commonly expressed in Svedberg units (S), where a typical large protein complex is about 3–5S, a proteasome is 26S, and a eukaryotic ribosome is 80S.

Differential Centrifugation

The most common initial step in protein purification from cells or tissues is the separation of water-soluble proteins from insoluble cellular material by *differential centrifugation*. A starting mixture,

commonly a cell homogenate (mechanically broken cells), is poured into a tube and spun at a rotor speed, and for a period of time that forces cell organelles such as nuclei as well as large unbroken cells or large cell fragments to collect as a pellet at the bottom; the soluble proteins remain in the liquid in the tube above the pellet, which is called the *supernatant* (Figure 3-40a). The supernatant then is poured off, and either it or the pellet can be subjected to other purification methods to separate the many different proteins that they contain.

EXPERIMENTAL FIGURE 3-40 Centrifugation techniques separate particles that differ in mass or density. (a) In differential centrifugation, a cell homogenate or other mixture is spun long enough to sediment the larger particles (e.g., cell organelles, cells), which collect as a pellet at the bottom of the tube (step 2). The smaller particles (e.g., soluble proteins, nucleic acids) remain in the liquid supernatant, which can be transferred to another tube (step 3). (b) In rate-zonal centrifugation, a mixture is spun (step 1) just long enough to separate molecules that differ in mass but may be similar in shape and density (e.g., globular proteins, RNA molecules) into discrete zones within a density gradient commonly

formed by a concentrated sucrose solution. Fractions are removed from the bottom of the tube and subjected to testing (assayed).

Rate-Zonal Centrifugation

On the basis of differences in their masses, water-soluble proteins can be separated by centrifugation through a solution of increasing density, called a *density gradient*. A concentrated sucrose solution is commonly used to form a density gradient in a centrifuge tube (with higher concentrations of sucrose, and thus a higher solution density, toward the bottom of the tube, Figure 3-40b). When a protein mixture is placed on top of a sucrose density gradient in a tube and subjected to centrifugation, each protein in the mixture migrates down the tube at a rate controlled by the protein's physical properties. All the proteins start from the thin layer of the sample that was placed at the top of the tube and separate into bands (actually, disks) of proteins of different masses as they travel at different rates through the gradient. In this separation technique, called *rate-zonal centrifugation*, samples are centrifuged just long enough to separate the molecules of interest into discrete bands, also called *zones* (Figure 3-40b). If a sample is centrifuged for too short a time, the different protein molecules will not separate sufficiently. If a sample is centrifuged much longer than necessary, all the proteins will end up mixed together at the bottom of the tube.

Although the sedimentation rate is strongly influenced by particle mass, rate-zonal centrifugation is seldom effective in determining precise molecular weights because variations in shape also affect the sedimentation rate. The exact effects of shape are hard to assess, especially for proteins or other molecules, such as single-stranded nucleic acid molecules, that can assume many complex shapes. Nevertheless, rate-zonal centrifugation has proved to be a practical method for separating many different types of polymers and particles. A second density-gradient technique, called *equilibrium density-gradient centrifugation*, is used mainly to separate DNA, lipoproteins that carry lipids through the circulatory system, or organelles (see Figure 4-37).

Electrophoresis Separates Molecules on the Basis of Their Charge-to-Mass Ratio

Electrophoresis, a technique for separating molecules in a mixture under the influence of an applied electric field, is one of the most frequently used techniques to study proteins and nucleic acids. Dissolved molecules in an electric field move, or migrate, at a speed determined by their charge-to-mass (charge:mass) ratio and the physical properties of the medium through which they migrate. For example, if two molecules have the same mass and shape, the one

with the greater net charge will move faster toward an electrode of the opposite polarity.

SDS-Polyacrylamide Gel Electrophoresis

Because many proteins or nucleic acids that differ in size and shape have nearly identical charge:mass ratios, electrophoresis of these macromolecules in a liquid solution results in little or no separation of molecules of different lengths. However, successful separation of proteins and nucleic acids can be accomplished by electrophoresis in various gels (semisolid suspensions in water similar to the congealed gelatin found in desserts). These gels are commonly cast into flat, relatively thin slabs between a pair of glass plates. When a mixture of proteins is placed in a gel and an electric current is applied, the gel acts as a sieve, allowing smaller species to maneuver more rapidly through its pores than larger species do. The shape of a molecule can also influence its rate of migration (long, asymmetric molecules migrate more slowly than spherical ones of the same mass).

Electrophoretic separation of proteins is most commonly performed in polyacrylamide gels. These gels are made by polymerizing a solution of acrylamide monomers into polyacrylamide chains and simultaneously cross-linking the chains into a semisolid matrix. The pore size of a gel can be varied by adjusting the concentrations of polyacrylamide and the cross-linking reagent. The rate at which a protein moves through a gel is influenced by the gel's pore size and

the strength of the electric field. By suitable adjustment of these parameters, proteins of widely varying sizes can be resolved (separated from one another) by this technique, known as *p*oly*a*crylamide *g*el *e*lectrophoresis (PAGE).

In the most powerful technique for resolving protein mixtures, proteins are exposed to the ionic detergent SDS (sodium dodecyl sulfate) before and during gel electrophoresis (Figure 3-41). SDS denatures proteins, in part because it binds to hydrophobic side chains, destabilizing the hydrophobic interactions in the core of a protein that contribute to its stable conformation. SDS treatment is usually combined with heating, often in the presence of reducing agents that break disulfide bonds. Under these conditions, most multimeric proteins dissociate into their subunits. Typically, the amount of SDS that binds to the protein is proportional to the length of the polypeptide chain and relatively independent of the sequence. Two proteins of similar size will bind the same absolute quantity of SDS, whereas a protein twice that size will bind twice the amount of SDS. Denaturation of a complex protein mixture with SDS in combination with heat usually forces each polypeptide chain into an extended conformation and imparts on each of the proteins in the mixture a constant charge:mass ratio because the dodecyl sulfate, which is negatively charged, is the major contributor of charge. As the SDS-bound proteins move through the polyacrylamide gel, they are separated according to size by the sieving action of the gel. SDS treatment thus eliminates the effect of differences in native

conformation; therefore, chain length, which is proportional to mass, is the principal determinant of the migration rate of proteins in *SDS-polyacrylamide electrophoresis (SDS-PAGE)*. Even chains that differ in molecular weight by less than 10 percent can be resolved by this technique. Moreover, the molecular weight of a protein can be estimated by comparing the distance that it migrates through a gel with the distances that proteins of known molecular weight (called molecular weight "standards") migrate in the same gel (there is a roughly linear relationship between migration distance and the log of the molecular weight). Proteins within the gels can be extracted for further analysis (e.g., identification by the methods described below).

EXPERIMENTAL FIGURE 3-41 SDS-polyacrylamide gel electrophoresis (SDS-PAGE) separates proteins primarily on the basis of their masses. (a) Initial

treatment with SDS, a negatively charged detergent, dissociates multimeric proteins and denatures all the polypeptide chains (step **1**). During electrophoresis, the SDS-protein complexes migrate through the polyacrylamide gel (step **2**). Small complexes are able to move through the pores faster than larger ones. Thus the proteins separate into bands according to their sizes as they migrate. The separated protein bands are visualized by staining with a dye (step **3**). (b) Example of SDS-PAGE separation of all the proteins in a whole-cell lysate (detergent-solubilized cells). *Left*: The many separate stained proteins appear almost as a continuum. *Right*: A single protein purified from the lysate by a single step of antibody-affinity chromatography. The proteins were visualized by staining with a silver-based dye.

[Part (b) Data from B. Liu and M. Krieger, 2002, *J. Biol. Chem*. **277**:34125–34135.]

If two or more polypeptides are cross-linked by disulfide bonds, the protein's migration rate in SDS-PAGE will depend on whether or not the protein has been reduced to break those bonds prior to electrophoresis. The cross-linked proteins will appear larger than the individual, reduced subunits. By examining samples with and without reduction, one can identify such proteins and their component polypeptides.

Two-Dimensional Gel Electrophoresis

Electrophoresis of a complex biological mixture of proteins, for example, purified organelles or even whole cells or tissues, by SDS-PAGE can separate proteins having relatively large differences in mass, but cannot readily resolve proteins having similar masses (e.g., a 41-kDa protein versus a 42-kDa protein). To separate proteins of similar masses, another physical characteristic must be exploited.

Most commonly, this characteristic is electric charge, which is determined by the pH of the sample and by the relative number of the protein's positively and negatively charged groups, which is in turn dependent on the pK_a's of the ionizable groups (see Chapter 2) on the proteins (usually the amino and carboxyl termini and side chains such as those in lysine and aspartic acid). Two unrelated proteins having similar masses are unlikely to have identical net charges because their sequences, and thus the number of acidic and basic residues, are different.

In *two-dimensional gel electrophoresis*, proteins are separated sequentially, first by their charges using a very sensitive method called *isoelectric focusing (IEF)* and then by their masses using SDS electrophoresis. Isoelectric focusing (IEF) separates proteins on the basis of their **isoelectric points (pI**, Figure 3-42) and can clearly separate (resolve) proteins that differ by only one charge unit. Two-dimensional gel electrophoresis is sensitive enough to separate phosphorylated and nonphosphorylated versions of the same protein. Today sophisticated mass spectrometry methods, described below, are often used in place of two-dimensional gel electrophoresis, both to separate and to identify the protein components of a complex sample as well as to compare changes in the amounts of those components in different biological specimens.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 3-42 Two-dimensional gel electrophoresis separates proteins on the basis of charge and mass. In this technique, proteins are first separated into bands on the basis of their charges by isoelectric focusing (IEF, step 1). For the first step using IEF, a cell or tissue extract is fully denatured by high concentrations (8 M) of urea (and sometimes SDS) and then layered on a strip of gel that contains urea, which removes any bound SDS. The gel contains a continuous pH gradient along its length ranging from pH 3 to pH 10 formed by ampholytes, which are polyanionic, and polycationic small molecules that are cast into the gel. When an electric field is applied to the gel, the ampholytes will migrate. Ampholytes with an excess of negative charges will migrate toward the anode (upward in step 1), where they establish an acidic pH (many protons),

while ampholytes with an excess of positive charges will migrate toward the cathode, where they establish an alkaline pH. The careful choice of the mixture of ampholytes and careful preparation of the gel allow the construction of stable pH gradients ranging from pH 3 to pH 10. A charged protein placed at one end of such a gel will migrate through the gradient under the influence of the electric field until it reaches its isoelectric point (pI), the pH at which the net charge of the protein is zero. With no net charge, the protein will migrate no further, forming a band or thin strip in the gel strip. To achieve the second dimension of separation, the resulting gel strip is applied to an SDS-polyacrylamide gel (step 2) to permit separation of the proteins on the basis of their molecular weights. The IEF gel strip is placed lengthwise on one outside edge of a square or rectangular slab of polyacrylamide gel, this time saturated with SDS to confer on each separated protein a more or less constant charge:mass ratio. When an electric field is imposed, the proteins will migrate from the IEF gel into the SDS gel and then separate according to their masses to form spots in two dimensions defined by their pI and molecular weight (step 3). The polypeptide spots can be visualized either by staining with dyes or, if the proteins are radioactive, by autoradiography.

Liquid Chromatography Resolves Proteins by Mass, Charge, or Affinity

A third common technique for separating mixtures of proteins or fragments of proteins, as well as other molecules, is based on the principle that molecules in solution can differentially interact with (bind to and dissociate from) a particular solid surface, depending on the physical and chemical properties of the molecule and the surface. If the solution is allowed to flow across the surface, then molecules that interact frequently with the surface will spend more

time bound to (or retained at) the surface, and thus flow past the surface more slowly, than molecules that interact infrequently with it. In this technique, called **liquid chromatography (LC)**, the sample is placed on top of a tightly packed column of spherical beads held within a glass, metal, or plastic cylinder (Figure 3-43). The sample then flows down the column, driven by gravitational or hydrostatic forces alone or sometimes with the assistance of a pump. In some LC systems, the composition of the fluid flowing out of the column is monitored continuously (e.g., by spectroscopy). Small aliquots of fluid flowing out of the column, called *fractions*, are collected sequentially and can be analyzed subsequently for their contents and chemical activities (e.g., enzymatic activity). The nature of the beads in the column determines whether the separation of proteins depends on differences in their mass, charge, or other binding properties (e.g., affinity for substances attached to the beads).

EXPERIMENTAL FIGURE 3-43 Three commonly used liquid chromatographic techniques separate proteins on the basis of mass, charge, or affinity for a specific binding partner. (a) Gel filtration chromatography separates proteins that differ in size. A mixture of proteins is carefully placed, or loaded, on the top of a cylinder packed with porous beads. Smaller proteins travel through the column more slowly than larger proteins. Thus the different proteins emerging in the eluate flowing out of the bottom of the column at different times (different elution volumes) can be collected in separate tubes, called *fractions*. (b) Ion-exchange chromatography separates proteins that differ in net charge in columns packed with beads that carry either a positive charge (shown here) or a negative charge. Proteins having the same net charge as the beads are repelled and flow through the column, whereas proteins having the opposite charge bind to the beads more or less tightly, depending on their structures. Bound proteins — in this case, negatively charged proteins — are subsequently eluted by passing a salt gradient (usually of NaCl or KCl) through the column.

As the ions bind to the beads, they displace the proteins; more tightly bound proteins require higher salt concentrations in order to be released. (c) In antibody-affinity chromatography, a mixture of proteins is passed through a column packed with beads to which a specific antibody is covalently attached. Only proteins with high affinity for the antibody are retained by the column; all the nonbinding proteins flow through. After the column is washed, the bound protein is eluted with an acidic solution or some other solution that disrupts the antigen-antibody complexes; the released protein then flows out of the column and is collected.

Gel Filtration Chromatography

Proteins that differ in mass can be separated on a column of porous beads made from polyacrylamide, dextran (a bacterial polysaccharide), or agarose (a seaweed derivative) — a technique called *gel filtration chromatography*. Although proteins flow around the beads, they spend some time within the large depressions that cover a bead's surface. Because smaller proteins can penetrate these depressions more readily than larger proteins can, they travel through a gel filtration column more slowly than do larger proteins (Figure 3-43a). (In contrast, proteins migrate *through* the pores in an electrophoretic gel; thus smaller proteins move faster than larger ones.) The total volume of liquid required to elute (or separate and remove) a protein from a gel filtration column depends on the protein's mass: the smaller its mass, the longer it is trapped on the beads, the longer it takes to traverse the column, and the greater the elution volume. If proteins of known mass are used as standards to calibrate the column, the elution volume can be used to estimate the mass of a protein in a mixture. A protein's shape, whether is it

elongated or compact, as well as its mass can influence the elution volume.

Ion-Exchange Chromatography

In ion-exchange chromatography, proteins are separated on the basis of differences in their charges. This technique makes use of specially modified beads whose surfaces are covered by amino groups or carboxyl groups and thus carry either a positive charge (NH_3^+) or a negative charge (COO^-) at neutral pH.

The proteins in a mixture carry various net charges at any given pH. When a solution of mixed proteins flows through a column of positively charged beads, only proteins with a net negative charge (acidic proteins) adhere to the beads; neutral and positively charged (basic) proteins flow unimpeded through the column (Figure 3-43b). The acidic proteins are then eluted selectively from the column by passing a solution of increasing concentrations of salt (a salt gradient) through the column. At low salt concentrations, protein molecules and beads are attracted by their opposite charges. At higher salt concentrations, negatively charged salt ions bind to the positively charged beads, displacing the negatively charged proteins. In a gradient of increasing salt concentrations, weakly bound proteins — those with a relatively low charge — are eluted first, and highly charged proteins are eluted last. Similarly, a negatively

charged column can be used to retain and fractionate basic (positively charged) proteins.

Affinity Chromatography

The ability of proteins to bind specifically to other molecules is the basis of affinity chromatography. In this technique, ligands or other molecules (affinity reagents) that bind to the protein of interest are covalently attached to the beads used to form the column. Ligands can be enzyme substrates, inhibitors or their analogs, or other small molecules that bind to specific proteins. In a widely used form of this technique — *antibody-affinity*, or *immunoaffinity, chromatography* — the molecule attached to the beads is an antibody specific for the desired protein (Figure 3-43c). (We discuss antibodies as tools for studying proteins next; see also Chapter 24, which describes how antibodies are made.)

In principle, an affinity column will retain only those proteins that bind the molecule attached to the beads; the remaining proteins, regardless of their charges or masses, will pass through the column because they do not bind. In this way, a single type of protein can be isolated from a very complex biological mixture, including whole cells or tissues, in a single step. However, if a retained protein is in turn bound to other molecules, forming a complex, then the entire complex is retained on the column. The proteins bound to the affinity column are then eluted by adding an excess of a soluble

form of the ligand, by exposure of bound materials to detergents, or by changing the salt concentration or pH such that the binding to the molecule on the column is disrupted. The ability of this technique to separate particular proteins depends on the selection of appropriate binding partners that bind more tightly to the protein of interest than to other proteins.

One variation of affinity chromatography is to covalently modify a protein of interest with some compound that in turn can bind to an affinity reagent on a bead. For example, a small molecule such as biotin (vitamin B) can be chemically cross-linked to a protein and then that modified protein can be affinity purified by a column whose beads are linked to the bacterial protein streptavidin that binds biotin exceedingly tightly. Alternatively, a gene can be engineered to express as a single polypeptide chain a chimeric, or fusion, protein comprising a protein of interest together with a peptide or protein that can bind tightly to an affinity reagent attached to a bead. Fusion proteins containing the enzyme glutathione-S-transferase (GST) can be affinity purified using beads linked to the small molecule glutathione. Fusion proteins containing a short peptide of polyhistidine residues can be purified using beads linked to divalent metals such as Ni^{2+} or Zn^{2+}. Fusion proteins containing a short peptide can be purified using beads linked to an antibody that binds to that peptide.

Highly Specific Enzyme and Antibody Assays Can Detect Individual Proteins

The purification of a protein, or any other molecule, requires a specific *assay* that can detect the presence of that molecule as it is separated from other molecules (e.g., in column or density-gradient fractions or gel bands or spots). Such an assay capitalizes on some highly distinctive characteristics of a protein: the ability to bind a particular ligand, to catalyze a particular reaction, or to be recognized by a specific antibody. The assay must also be simple and fast to minimize errors and the possibility that the protein of interest will become denatured or degraded while the assay is being performed. The goal of any purification scheme is to isolate sufficient amounts of a given protein for study; thus a useful assay must also be sensitive enough that only a small proportion of the available material is consumed by it. Many common protein assays require just 10^{-9} to 10^{-12} g of material.

Chromogenic Enzyme Reactions

Many assays are tailored to detect some functional aspect of a protein. For example, assays of enzymatic activity are based on the ability to detect the loss of substrate or the formation of product. Some enzymatic activity assays use chromogenic substrates, which change color in the course of the reaction. (Some substrates are naturally chromogenic; those that are not can be linked to a

chromogenic molecule.) Because of the specificity of an enzyme for its substrate, only samples that contain the enzyme will change color in the presence of a chromogenic substrate; the rate of the change provides a measure of the quantity of enzyme present. Enzymes that catalyze chromogenic reactions can also be fused or chemically linked to an antibody and used to report the presence or location of an antigen to which the antibody binds (see the next page).

Antibody Assays

As noted earlier, antibodies have the distinctive characteristic of binding tightly and specifically to antigens. As a consequence, preparations of antibodies that recognize a protein antigen of interest can be generated and used to detect the presence of that protein, either in a complex mixture of other proteins (finding a needle in a haystack, as it were) or in a partially or completely purified preparation of a particular protein. The presence of the antigen can be detected by labeling the antibody with an enzyme, a fluorescent molecule, or a radioactive isotope, which can be detected using an enzyme assay, fluorescence microscopy or spectroscopy, or a radiation detector, respectively. For example, luciferase, an enzyme present in fireflies and some bacteria, can be linked to an antibody. In the presence of ATP and its substrate, luciferin, luciferase catalyzes a light-emitting reaction. In either case, after the antibody binds to the protein of interest (the antigen) and unbound antibody is washed away, substrates of the linked

enzyme are added and the appearance of color or emitted light is monitored. The intensity is proportional to the amount of enzyme-linked antibody, and thus antigen, in the sample. Alternatively, after a first (or "primary") antibody that is not otherwise labeled binds to its target protein, a second ("secondary"), labeled antibody that can recognize the first antibody is used to bind to the complex of the first antibody and its target. This combination of primary and secondary antibodies (sometimes called an antibody "sandwich") permits very high sensitivity in the detection of a target protein because the labeled secondary antibody is often a mixture of antibodies that bind to multiple sites on the first antibody and thus results in a stronger signal than would labeling of the primary antibody alone. It is important to remember that an antibody recognizes and binds to only its epitope on a target antigen. If that epitope is altered — for example, by partial unfolding or post-translational modifications — or is blocked when the antigen protein is bound to some other molecule, the ability of the antibody to bind may be reduced or completely lost. Thus the absence of antibody binding does not necessarily mean that the antigen is not present in a sample, only that the epitope portion of that antigen is not present or accessible for antibody binding.

To generate antibodies to a protein (discussed in detail in Chapter 24), the intact protein, or a fragment of the protein, is injected into an animal (usually a rabbit, mouse, or goat). Sometimes a short synthetic peptide of 10–15 residues based on the sequence of the protein of interest is injected as the antigen to induce antibody

formation. Such a synthetic peptide, when coupled to a large protein carrier, can induce an animal to produce antibodies that bind specifically to that part (the epitope) of the full-sized, natural protein. Biosynthetically or chemically attaching the epitope to an unrelated protein is called *epitope tagging*. As we'll see throughout this book, antibodies generated using either synthetic peptide epitopes or intact proteins are extremely versatile reagents for isolating, detecting, and characterizing proteins.

Detecting Proteins by Attaching Green Fluorescent Protein

An alternative to epitope tagging that is particularly useful in detecting specific proteins within live cells makes use of *green fluorescent protein (GFP)*, a naturally fluorescent protein found in jellyfish (see Figure 4-16). A chimeric protein containing both the protein of interest and GFP, linked together in one polypeptide chain, is expressed in cells by introducing into the cells a gene encoding the combined protein. The amounts and intracellular distribution of the chimeric protein can then be determined readily. This chimeric protein approach is described in Chapter 4.

Detecting Proteins in Gels

Proteins embedded within a gel usually are not visible. The two general approaches to detecting proteins in gels are either to label

or stain the proteins while they are still within the gel or to electrophoretically transfer the proteins to a membrane made of nitrocellulose or polyvinylidene difluoride and then detect them. Proteins within gels are usually stained with an organic dye or a silver-based stain, both of which are detectable with normal visible light, or with a fluorescent dye, which requires specialized detection equipment. Coomassie blue, the most commonly used organic dye, is typically used to detect about 1000 ng of protein, with a lower limit of detection of about 4–10 ng. Silver staining and fluorescence staining are more sensitive (with a lower limit of ~1 ng). Coomassie and other stains can also be used to visualize proteins after transfer to membranes; however, the most common method of visualizing proteins in membranes is immunoblotting.

Immunoblotting, also called *Western blotting*, combines the resolving power of gel electrophoresis with the specificity of antibodies. This multistep procedure is commonly used to separate proteins and then identify a specific protein of interest. As shown in Figure 3-44, two different antibodies are used, one that is specific for the protein of interest (primary antibody) and a secondary antibody that binds to the first and is linked to an enzyme or other molecule that permits detection of the first antibody (and thus the protein of interest to which it binds). The enzyme to which the second antibody is attached can either generate a visible colored product or, by a process called *chemiluminescence*, produce light that can readily be recorded by film or a sensitive electronic detector. An example of

the results of an immunoblotting experiment can be seen in Figure 15-10. If an antibody to the protein of interest is not available, but the gene encoding the protein is available and can be used to express the protein, then recombinant DNA methods (see Chapter 5) can incorporate a small peptide epitope into the normal sequence of the protein (epitope tagging) that can be detected by a commercially available antibody to that epitope.

EXPERIMENTAL FIGURE 3-44 Immunoblotting (IB, or Western blotting) and co-immunoprecipitation (co-IP) can detect specific proteins and their binding partners. (a) Immunoblotting method. Step 1: After a protein mixture has been electrophoresed through an SDS gel, the separated bands (or spots, for two-dimensional gel electrophoresis) are transferred (blotted) from the gel onto a porous membrane. Individual proteins (blue ovals) are not visible at this stage. Step 2: The membrane is flooded with a solution of an antibody (Ab_1) specific for the protein of interest and allowed to incubate. Ab_1 binds to the protein of interest (second from the top), but not to any other proteins attached to the membrane, forming a layer of antibody molecules coincident with the protein (whose position still cannot be seen at this point). The membrane is washed to remove unbound

Ab_1. Step **3**: The membrane is incubated with a second antibody (Ab_2) that specifically recognizes and binds to the first (Ab_1). This second antibody is covalently linked to an enzyme that catalyzes a chromogenic reaction or releases light (e.g., chemiluminescence), a radioactive isotope, or some other substance whose presence can be detected with great sensitivity. Step **4**: Finally, the location and amount of bound Ab_2 are detected (e.g., by its color for a chromogenic reaction or by detectors or film that measure the light released by chemiluminescence). The mass of the protein of interest is determined by its electrophoretic mobility and its quantity by the band's intensity. (b) Immunoblotting was used to detect intracellular receptors and the influence of exposure to a ligand for one of the receptors. In this experiment, cells that are precursors to red blood cells were maintained in vitro in petri dishes and then treated with either no ligand ($-$, leftmost and rightmost lanes) or a ligand that binds to GR, the glucocorticoid receptor ($+$, duplicate samples in the two center lanes). The cells were then lysed in detergent, and immunoblotting was performed on the total cell lysates using three different antibodies: to the GR receptor (anti-GR), to a receptor called *PPARα* (anti-PPARα), or to actin, an abundant intracellular protein whose abundance was not expected to be sensitive to treatment with the ligand. [In these experiments, to compare the intensities of the bands in different lanes of the gel (representing the abundance of the corresponding protein in each sample), equal amounts of cell lysate must be loaded into each lane. The "loading control" in this experiment is the amount of actin seen in each lane. Because the intensities of the bands detected using the anti-actin antibody (bottom row) were equal, we can conclude that equal amounts of the different cell lysates were loaded into each lane of the gel. Thus it is valid to compare the band intensities between lanes.] The approximately equal intensities of the bands for both GR and PPARα with or without prior incubation of the cells with the GR ligand showed that the ligand did not substantially alter the amounts of either of these proteins in the cells. Portions of the same cell lysates used for the immunoblotting in part (b) were also used for the immunoprecipitation/immunoblotting shown in part (c). (c) Immunoprecipitation (IP) followed by immunoblotting (together called *co-IP*) was used to determine if the GR ligand can induce formation of a stable complex that contains both GR and PPARα. Portions of the cell lysates were immunoprecipitated with an antibody to GR (left and center lanes) or a control antibody (right lane) that cannot bind to either GR or PPARα. The immunoprecipitates were separated from the rest of the lysates by centrifugation and then analyzed by immunoblotting with either anti-GR (top box) or anti-PPARα (bottom box). As expected, the top box shows that the GR protein was detected in the immunoprecipitates generated using the α-GR when the same anti-GR antibody was used for the immunoblotting, but not in the immunoprecipitates generated with the control antibody

(no band observed). Strikingly, when one examines the immunoprecipitates by immunoblotting with the anti-PPARα antibody (bottom box), a substantial amount of PPARα is seen when the GR ligand is present (center lanes), whereas little co-precipitates in the absence of the GR ligand (left lane) or in the control immunoprecipitate (right lane). These results indicate that the GR ligand induces formation of a complex containing both the glucocorticoid receptor and the PPARα proteins. These results do not establish whether or not the GR and PPARα proteins bind directly to each other when the GR ligand is present or if there are additional molecules in the complex that act as intermediates holding the GR and PPARα tightly together when the ligand is present.

Immunoprecipitation

Immunoprecipitation, often abbreviated as **IP**, exploits the specificity of antibodies to separate a protein of interest from other molecules in a complex mixture — for example, all proteins extracted from a sample of cells or a sample of blood. An antibody to the protein of interest is added to a sample, and the antibody is given time to bind to epitopes on the target protein. An agent that binds to the antibody is then added to cause the antibody and its bound target to precipitate out of solution into particles that can be isolated by centrifugation. Detailed examples of this technique are described in Figure 3-44 and Chapter 15. The precipitate is then solubilized under denaturing conditions — for example, in a detergent-containing buffer — to separate the antibody from the protein, and the immunoprecipitated target protein can then be analyzed. If the immunoprecipitated target is tightly bound to one or

more other molecules, those bound molecules may be precipitated along with the protein of interest (*co-immunoprecipitation*, sometimes abbreviated as *co-IP*). The co-IP method is used frequently to identify and characterize quaternary structures and supramolecular complexes.

Radioisotopes Are Indispensable Tools for Detecting Biological Molecules

A sensitive method for tracking a protein or other biological molecule is by detecting the radioactivity emitted from a radiolabel introduced into the molecule. In a radiolabeled molecule, at least one atom is present in a radioactive form, called a **radioisotope**.

Radioisotopes Useful in Biological Research

Hundreds of biological molecules (e.g., amino acids, nucleosides, and numerous other small-molecule metabolites) labeled with various radioisotopes are commercially available. These preparations vary considerably in their *specific activity*, which is the amount of radioactivity per unit of material, measured in disintegrations per minute (dpm) per millimole (mmol). The specific activity of a labeled compound depends on the radioisotope's *half-life*, the time required for half the atoms to undergo radioactive decay, which releases the detectable radiation. In general, the

shorter the half-life of a radioisotope, the higher its specific activity (Table 3-1). The specific activity of a labeled compound must be high enough for accurate detection of its emitted radiation.

TABLE 3-1 • Radioisotopes Commonly Used in Biological Research

Isotope	Half-Life
Phosphorus-32	14.3 days
Iodine-125	60.4 days
Sulfur-35	87.5 days
Tritium (hydrogen-3)	12.4 years
Carbon-14	5730.4 years

A common approach to radiolabeling macromolecules (proteins, RNA, DNA) in cells is to add a radiolabeled biosynthetic precursor to the extracellular medium [e.g., ^{3}H- or ^{35}S-labeled amino acids, ^{32}P-labeled phosphate (precursor for ^{32}P-labeled ATP), or ^{3}H-labeled nucleic acid precursors such as deoxythymidine (also simply called thymidine)]. The precursor enters the cells via transporters (see Chapter 11) and is incorporated into newly synthesized macromolecules by the cells (see Chapter 5). For example, methionine and cysteine labeled with sulfur-35 (^{35}S) are widely used to label cellular proteins because preparations of these amino acids with high specific activities ($>10^{15}$ dpm/mmol) are available. Kinases within cells (or used in vitro) can transfer a ^{32}P-labeled

phosphate from ^{32}P-labeled ATP to label phosphoproteins. In intact cells, ^{32}P-labeled phosphate added to the medium is taken up via phosphate transporters and then incorporated into various phosphate containing molecules, including ATP. Likewise, commercial preparations of ^{3}H-labeled nucleic acid precursors have much higher specific activities than those of the corresponding ^{14}C-labeled preparations. In most experiments, the former are preferable because they allow RNA or DNA to be adequately labeled a shorter time after incorporation or require a smaller cell sample. Various phosphate-containing compounds in which the phosphorus atom is the radioisotope phosphorus-32 are readily available. Because of their high specific activity, ^{32}P-labeled nucleotides are routinely used to label nucleic acids in cell-free systems.

Labeled compounds in which a radioisotope replaces atoms normally present in the molecule have virtually the same chemical properties as the corresponding unlabeled compounds. Enzymes, for instance, generally cannot distinguish between substrates labeled in this way and their unlabeled substrates. The presence of such radioactive atoms is indicated with the isotope in brackets (no hyphen) as a prefix (e.g., [^{3}H]leucine). In contrast, labeling of almost any biomolecule (e.g., protein or nucleic acid) with the radioisotope iodine-125 (^{125}I) requires the covalent addition of ^{125}I to a molecule that normally does not have iodine as part of its structure. Because this labeling procedure modifies the chemical structure, the biological activity of the labeled molecule may differ somewhat

from that of the unlabeled form. The presence of such radioactive atoms is indicated with the isotope as a prefix followed a hyphen (no bracket) (e.g., ^{125}I-trypsin). Standard methods for labeling proteins with ^{125}I result in covalent attachment of the ^{125}I primarily to the aromatic rings of tyrosine side chains (mono- and diiodotyrosine). Nonradioactive isotopes are finding increasing use in cell biology, especially in nuclear magnetic resonance studies and in mass spectroscopy applications, as will be explained below.

Labeling Experiments and Detection of Radiolabeled Molecules

Whether labeled compounds are detected by **autoradiography** — exposure of the sample on a two-dimensional detector (photographic emulsion or electronic detector) — or their radioactivity is measured in an appropriate *counter*, the amount of a radiolabeled compound in a sample can be determined with great precision.

In one use of autoradiography, a tissue, cell, or cell constituent is labeled with a radioactive molecule, unassociated radioactive material is washed away, and the structure of the sample is stabilized either by chemically cross-linking the macromolecules in the sample ("fixation") or by freezing it. The sample is then overlaid with a photographic emulsion that is sensitive to radiation. Development of the emulsion yields small silver grains whose

distribution corresponds to that of the radioactive material and is usually detected by microscopy. Autoradiographic studies of whole cells were crucial in determining the intracellular sites where various macromolecules are synthesized and the subsequent movements of those macromolecules within cells. Various techniques employing fluorescence microscopy, which we describe in Chapter 4, have largely supplanted autoradiography for studies of this type. However, autoradiography is sometimes used in various assays for detecting specific, isolated DNA or RNA sequences at specific tissue locations (see Chapter 6) in a technique referred to as in situ hybridization.

Quantitative measurements of the amount of radioactivity in a labeled material are performed with several different instruments. A Geiger counter measures ions produced in a gas by the β particles or γ rays emitted from a radioisotope. These instruments are mostly handheld devices used to monitor radioactivity in the laboratory to protect investigators from excess exposure. In a scintillation counter, a radiolabeled sample is mixed with a liquid containing a fluorescent compound that emits a flash of light when it absorbs the energy of the β particles or γ rays released in the decay of the radioisotope; a phototube in the instrument detects and counts these light flashes. Phosphorimagers detect radioactivity using a two-dimensional array detector, storing digital data on the number of disintegrations per minute per small pixel of surface area. These instruments, which can be thought of as a kind of reusable electronic film, are commonly used to quantify radioactive

molecules separated by gel electrophoresis and are replacing photographic emulsions for this purpose.

Combinations of labeling and biochemical techniques and of visual and quantitative detection methods are often employed in labeling experiments. For instance, to identify the major proteins synthesized by a particular cell type, a sample of the cells is incubated with a radiolabeled amino acid (e.g., [^{35}S] methionine) for a few minutes, during which time the labeled amino acid enters the cells and mixes with the cellular pool of unlabeled amino acids, and some of it is biosynthetically incorporated into all newly synthesized proteins. Subsequently, unincorporated radiolabeled amino acid is washed away from the cells. The cells are harvested, and the mixture of cellular proteins is extracted from the cells (e.g., by a detergent solution) and then separated by any of the methods commonly used to resolve complex protein mixtures into individual components. Gel electrophoresis in combination with autoradiography or phosphorimager analysis is often the method of choice. The radioactive bands in the gel correspond to newly synthesized proteins, which have incorporated the radiolabeled amino acid. To detect a specific protein of interest, rather than the entire ensemble of biosynthetically radiolabeled proteins, a specific protein can be isolated by immunoprecipitation. The precipitate is then solubilized, for example, in an SDS-containing buffer, and the sample is analyzed by SDS-PAGE followed by autoradiography to detect the protein that is radioactively labeled. In this type of

experiment, a fluorescent compound that is activated by the radiation ("scintillator") may be infused into the gel on completion of the electrophoretic separation so that the light emitted can be used to detect the presence of the labeled protein, using either film or a two-dimensional electronic detector. An example is shown in the experiment described in Figure 3-45. This method is particularly useful for weak β emitters such as ^{3}H.

EXPERIMENTAL FIGURE 3-45 Pulse-chase experiments can track the pathway of protein modification within cells. (a) To follow the fate of a specific newly synthesized protein in cells, cells were incubated with [^{35}S]methionine for 0.5 hours (the pulse) to label all newly synthesized proteins, and any radioactive amino acid not incorporated into the cells was then washed away. The cells were further incubated (the chase) for varying times up to 24 hours, and samples from each time point of the chase were subjected to

immunoprecipitation to isolate one specific protein (here the low-density lipoprotein receptor). SDS-PAGE of the immunoprecipitates followed by autoradiography permitted visualization of the target protein, which is initially synthesized as a small precursor (*p*) and then rapidly modified to a larger mature form (*m*) by addition of carbohydrates. About half of the labeled protein was converted from *p* to *m* during the pulse; the rest was converted after 0.5 hours of chase. The protein remained stable for 6–8 hours before it began to be degraded within cells (as indicated by reduced band intensity). (b) The same experiment was performed in cells in which a mutant form of the protein is made. The mutant *p* form cannot be properly converted to the *m* form, and it is more quickly degraded than the normal protein.

[©1986 Kozarsky et al. *J .Cell Biol.* **102**:1567–1575. doi:10.1083/jcb.102.5.1567]

Pulse-chase experiments are particularly useful for tracing changes in the intracellular location of proteins or the modification of a protein or metabolite over time. In this experimental protocol, a cell sample is exposed to a radiolabeled compound that can be incorporated into or otherwise attached to a cellular molecule of interest — the *pulse* — for a brief period. The pulse ends when the unincorporated radiolabeled molecules are washed away and the cells are exposed to a vast excess of the identical, but unlabeled, compound to dilute the radioactivity of any remaining, but unincorporated, radiolabeled compound. This procedure prevents any incorporation of significant amounts of radiolabel after the pulse period and initiates the *chase* period (see Figure 3-45). Samples taken periodically during the chase period are assayed to determine the location or chemical form of the radiolabel as a function of time. Pulse-chase experiments in which the radiolabeled protein is detected by autoradiography after immunoprecipitation and SDS-

PAGE are often used to follow the rate of synthesis, modification, and degradation of proteins. In these experiments, radiolabeled amino acid precursors are added during the pulse, and the amounts and characteristics of the radiolabeled target protein are detected during the chase. One can thus observe postsynthetic modifications of the protein, such as the covalent addition of sugars (see Chapters 13 and 14) or proteolytic cleavage, that change its electrophoretic mobility, as well as the rate of degradation of the protein, which is detected as the loss of signal with increasing time of chase. A classic use of the pulse-chase technique with autoradiography was in studies that elucidated the pathway traversed by secreted proteins from their site of synthesis in the endoplasmic reticulum to the cell surface (see Chapter 14).

Mass Spectrometry Can Determine the Mass and Sequence of Proteins

Mass spectrometry (MS) is a powerful technique for characterizing proteins, especially for determining the mass of a protein or fragments of a protein. With such information in hand, it is also possible to determine part or all of the protein's sequence. This method permits the accurate direct determination of the ratio of the mass (m) of a charged molecule (a molecular ion) to its charge (z), or m/z. Additional techniques are then used to deduce the absolute mass of the molecular ion.

All mass spectrometers have four key features. The first is an ion source, from which charge, usually in the form of protons, is transferred to the peptide or protein molecules under study, causing them to become ionized. The conversion of polypeptide molecules to ions occurs in the presence of a high electric field, which directs the charged molecular ions into the second key component, the mass analyzer. The mass analyzer, which is always in a high vacuum chamber, physically separates the ions on the basis of their differing mass-to-charge (*m/z*) ratios. The separated ions are subsequently directed to strike a detector, the third key component, which provides a measure of the *m/z* ratio of each ion in the sample and the relative abundances of those ions. The fourth essential component is a computerized data system that is used to calibrate the instrument; to acquire, store, and process the resulting data; and often to direct the instrument to automatically collect additional specific types of data from the sample, based on the initial observations. This type of automated feedback is used for the tandem MS (MS/MS) peptide-sequencing methods described below.

The two most frequently used methods of generating ions of proteins and protein fragments are (1) matrix-assisted laser desorption/ionization (MALDI) and (2) electrospray (ES). In MALDI (Figure 3-46), the peptide or protein sample is mixed with the matrix — a low-molecular-weight organic acid that absorbs UV light — and the mixture is dried onto a metal target. Energy from a UV laser is absorbed by the matrix and converted into heat. As a consequence,

the sample vaporizes and the protein sample is ionized by protonation, producing singly charged molecular ions from the constituent molecules. In ES (Figure 3-47a), a sample of peptides or proteins in solution is converted into a fine mist of tiny droplets by spraying through a narrow capillary at atmospheric pressure. The droplets are formed in the presence of a high electric field, which renders them highly charged. The solvent evaporates from the droplets in their short flight (mm) to the entrance of the mass spectrometer's mass analyzer, forming multiply charged ions from the peptides and proteins. The gaseous ions enter the mass analyzer, where they are accelerated by electric fields and separated on the basis of their m/z.

EXPERIMENTAL FIGURE 3-46 Molecular mass can be determined by matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry. In a MALDI-TOF mass spectrometer, pulses of light from a laser

ionize a protein or peptide mixture that is absorbed on a metal target (step 1). An electric field in the mass analyzer accelerates the ions in the sample toward the detector (steps 2 and 3). The time it takes an ion to reach the detector is proportional to the square root of the mass-to-charge (m/z) ratio. Among ions having the same charge, the smaller ions move faster (shorter time to the detector). The molecular weight of each ion from the sample is calculated using the time of flight of a standard.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 3-47 Molecular mass of proteins and peptides can be determined by electrospray ionization ion-trap mass spectrometry. (a) Electrospray (ES) ionization converts proteins and peptides in a solution into highly charged gaseous ions by passing the

solution through a needle (forming the droplets) that has a high voltage across it (charging the droplets). Evaporation of the solvent produces gaseous ions that enter a mass spectrometer. The ions are analyzed by an ion-trap mass analyzer that separates the ions by their *m/z* ratios and then directs the ions to the detector. (b) *Top:* Mass spectrum of a mixture of three major and several minor peptides from the mouse H-2 class I histocompatibility antigen Q10 α chain. The data are presented as the relative abundance of the ions striking the detector (*y* axis) as a function of the mass-to-charge (*m*/*z*) ratio (*x* axis). *Bottom:* In an MS/MS instrument such as the ion trap shown in part (a), a specific peptide ion can be selected for fragmentation into smaller ions that are then analyzed and detected. The MS/MS spectrum (also called the *product-ion spectrum*) provides detailed structural information about the parent ion, including sequence information for peptides. Here the ion with an *m*/*z* of 836.47 was selected and fragmented and the *m*/*z* mass spectrum of the product ions measured. Note there is no longer an ion with an *m*/*z* of 836.47 present because it was fragmented. From the varying sizes of the product ions, the understanding that peptide bonds are often broken in such experiments, the known *m*/*z* values for individual amino acid fragments, and database information, the sequence of the peptide, FIIVGYVDDTQFVR, can be deduced.

[Part (b) Unpublished data from S. Carr.]

The two most frequently used types of mass analyzers are time-of-flight (TOF) instruments and ion traps. TOF instruments exploit the fact that the time it takes an ion to pass through the length of the mass analyzer before reaching the detector is proportional to the square root of *m/z* (smaller ions move faster than larger ones with the same charge; see Figure 3-46). In ion-trap analyzers, tunable electric fields are used to capture (or "trap") ions with a specific *m/z* and to sequentially pass the trapped ions out of the mass analyzer onto the detector in order of their *m/z* ratios (see Figure 3-47a). By varying the electric fields, researchers can examine ions with a wide range of *m/z* values one by one, producing a mass spectrum, which

is a graph of *m/z* (*x* axis) versus relative abundance, determined by the intensity of the signal measured by the detector (*y* axis) (Figure 3-47b, *top*).

In tandem, or MS/MS, instruments, any given parent ion in the original mass spectrum (see Figure 3-47b, *top*) can be chosen (mass-selected) for further analysis. The chosen ions are transferred into a second chamber in which they are broken into smaller fragment ions by collision with an inert gas, and then the *m/z* and relative abundances of the resulting fragment ions are measured in a second MS analyzer (Figure 3-47b, *bottom*; see also Figure 3-50). These multiple mass-analysis and fragmentation steps all take place within the same machine in about 0.1 seconds per selected parent ion. The fragmentation and subsequent mass analysis permit the sequences of short peptides (<25 amino acids) to be determined because collisional fragmentation occurs primarily at peptide bonds, so the differences in masses between the multiple ion fragments generated correspond to the in-chain masses of the individual amino acids, permitting deduction of the sequence in conjunction with database sequence information (see Figure 3-47b, *bottom*).

Mass spectrometry is highly sensitive, able to detect as little as $0.001–0.010 \times 10^{-18}$ mol (0.001–0.010 attomoles) of a peptide or 1×10^{-18} mol (1 attomole) of a protein of 200,000 MW. The accuracy of the measurements of mass are dependent on the specific mass analyzer used, but error rates are typically about +/− 5 ppm for

peptides and 0.05–0.1 percent for proteins. So sensitive are its measurements of mass that MS can readily distinguish between two peptides that are chemically identical yet differ only in that one of the peptides contains only atoms with the most common, *light* isotopes (e.g., ^{1}H, ^{12}C, ^{14}N) whereas the other contains one or more atoms with the corresponding *heavy*, stable isotopes (e.g., the nonradioactive isotopes ^{2}H, ^{13}C, ^{15}N).

As described in Section 3.6, one of the most frequent uses of MS is to analyze complex mixtures of proteins such as those from cells, tissues, or biofluids such as plasma. Most commonly, protein samples are digested by proteases, and the peptide digestion products are subjected to analysis by MS. An especially powerful application of MS is to take a complex mixture of proteins from a biological specimen and digest it with the enzyme trypsin, which hydrolyzes peptide bonds at lysine and arginine residues, or other proteases. Peptides in the resulting complex mixture are then separated using liquid chromatography. The fluid flowing out of the liquid chromatography column is transferred into an ES tandem mass spectrometer. This technique, which is called *LC-MS/MS* and is described in more detail below, permits the nearly continuous analysis of a very complex mixture of proteins.

The abundances of ions determined by mass spectrometry in any given sample are relative, not absolute, values. Therefore, if one wants to use MS to compare the absolute amounts of a particular

protein in two different samples (e.g., from a normal versus a mutant organism), it is necessary to have an internal standard in the samples — a molecule whose amounts do not differ between the two samples. One then determines the amounts of the protein (or peptide fragments of the protein) of interest relative to the amount of the standard in each sample. This approach permits quantitatively accurate comparisons of protein levels between samples. An alternative approach involves simultaneously comparing in a single MS analysis the amounts of proteins from two or more different cell or tissue samples that have been mixed together. The different samples might differ genetically (wild-type versus mutant cells, clinical samples from different patients) or might differ due to the application of different environmental conditions (e.g., drug or hormone treatments). This mixing approach is possible provided the *m/z* ratios of proteins or peptides in each sample can be distinguished by MS from the corresponding and chemically identical proteins or peptides in the other samples. To make it possible to distinguish identical proteins from different samples, chemical, enzymatic, or biosynthetic techniques are used to label the different samples with different stable isotopes (e.g., $^{1}H/^{2}H$, $^{12}C/^{13}C$, $^{14}N/^{15}N$). For example, cells or organisms can first be grown in the presence of amino acids containing either heavy or light isotope atoms so that these amino acids are biosynthetically incorporated into all the proteins of that sample. Cells are typically incubated with the heavy or light amino acids for five or more cell divisions to ensure that all proteins are thoroughly labeled. Proteins

from the two samples are then mixed together and digested into peptides, and the peptides analyzed simultaneously by mass spectrometry. Proteins and peptides derived from the heavy sample can be distinguished in the mass spectrometer from those from the other, light, sample because of their higher masses, but are otherwise chemically identical. This method is called *s*table *i*sotope *l*abeling with *a*mino *a*cids in *c*ell *c*ulture (SILAC).

Chemical methods with names such as iTRAQ and TMT permit investigators to attach chemically identical but isotopically distinct labels to the peptides in each of 4–16 distinct biological samples. After labeling, the samples are mixed together and then analyzed simultaneously by MS. The isotopically distinct tags permit one to determine the sample from which any peptide arose, even though all of the tagged samples were mixed together prior to MS analysis. As a consequence, the relative amounts of all detectable proteins in each of the different samples can be determined quickly, efficiently, and accurately. In this way, the effects of a genetic, environmental, or chemical (e.g., drug) perturbation of cells on the cellular proteins can be assessed. Later in this chapter, we will consider the importance of analyzing such perturbations on the abundances of many different proteins simultaneously.

Protein Primary Structure Can Be Determined by Chemical Methods and

from Gene Sequences

The classic method for determining the amino acid sequence of a protein is Edman degradation. In this procedure, the free amino group of the N-terminal amino acid of a polypeptide is labeled, and the labeled amino acid is then cleaved from the polypeptide and identified by high-pressure liquid chromatography. The polypeptide is left one residue shorter, with a new amino acid at the N-terminus. The cycle is repeated on the ever-shortening polypeptide until all the residues have been identified.

Before about 1985, biologists commonly used Edman degradation for determining protein sequences. Now, however, complete protein sequences usually are determined by analysis of genome and messenger RNA sequences. The complete genomes of many organisms have already been sequenced, and the database of genome sequences from humans and numerous model organisms is expanding rapidly. As discussed in Chapter 6, the sequences of proteins can be deduced from DNA sequences that are predicted to encode proteins.

A powerful approach for determining the primary structure of an isolated protein combines MS and the use of sequence databases. First, the peptide mass fingerprint of the protein is obtained by MS. A *peptide mass fingerprint* is the list of the molecular weights of peptides that are generated from the protein by digestion with a specific protease, such as trypsin. The molecular weights of the

parent protein and its proteolytic fragments are then used to search genome databases for any similar-sized protein with identical or similar peptide mass fingerprints. Mass spectrometry can also be used to directly sequence peptides using MS/MS, as described above.

Protein Conformation Is Determined by Sophisticated Physical Methods

In this chapter, we have emphasized that protein function is dependent on protein structure. Thus, to figure out exactly how a protein works, its three-dimensional structure must be determined. Determining a protein's conformation requires sophisticated physical methods and complex analyses of the experimental data. Here we briefly describe three methods used to generate three-dimensional models of proteins.

X-ray Crystallography

The use of **x-ray crystallography** to determine the three-dimensional structures of proteins was pioneered by Max Perutz and John Kendrew in the 1950s. In this technique, beams of x-rays are passed through a protein crystal, in which millions of protein molecules are precisely aligned with one another in a rigid crystalline array. The wavelengths of x-rays are about 0.1–0.2 nm, short enough to determine the positions of individual atoms in the

protein. The electrons in the atoms of the crystal scatter the x-rays, which produce a diffraction pattern of discrete spots when they are intercepted by photographic film or an electronic detector (Figure 3-48). Such patterns are extremely complex — composed of as many as 25,000 diffraction spots, or reflections, whose measured intensities vary depending on the distribution of the electrons in the sample, which is, in turn, determined by the atomic structure and three-dimensional conformation of the protein. Elaborate calculations and modifications of the protein (e.g., the binding of heavy metals) must be made to interpret the diffraction pattern and calculate the distribution of electrons (called the *electron density map*). A portion of an electron density map of a protein can be seen in Figure 2-9. With the three-dimensional electron density map in hand, one then fits a molecular model of the protein to match the electron density, and it is these models that one sees in many of the various diagrams of proteins throughout this book (e.g., see Figure 3-9). The process is analogous to reconstructing the precise shape of a rock from the ripples that it creates when thrown into a pond. The precision with which one can determine the structure of a molecule from x-ray crystallography depends on the quality of the crystals used for the analysis and on how flexible part or all of the molecule is within the crystal lattice. A commonly used measure of the precision of a structure is its *resolution* given in Angstrom units (Å). Very high resolution protein structures have a resolution of <1 Å (Figure 2-9), and the positions of individual atoms can be observed. In structures whose resolutions are between 1 and 3 Å, the positions of many side

chains are well determined but individual atom positions must be inferred. Although sometimes the structures of parts of the protein cannot be clearly defined, using x-ray crystallography, researchers are systematically determining the structures of representative types of most proteins. To date, more than 140,000 detailed three-dimensional structures, including more than 35,000 distinct protein sequences, have been established using x-ray crystallography. These structures can be found in the Research Collaboratory for Structural Bioinformatics Protein Data Bank (http://www.rcsb.org/pdb/home/home.do), each with its own "PDB" entry.

EXPERIMENTAL FIGURE 3-48 X-ray crystallography provides diffraction data from which the three-dimensional structure of a protein can be determined. (a) Basic components of an x-ray crystallographic determination. When a narrow beam of x-rays strikes a crystal, part of the beam passes straight through and the rest is scattered (diffracted) in various directions. The intensity of the diffracted waves, which form periodic arrangements of diffraction spots, is recorded on an x-ray film or with a solid-state electronic detector. (b) X-ray diffraction pattern for a protein crystal collected on a solid-state detector. From complex analyses of patterns of spots like this one, the locations of the atoms in a protein can be determined.

Cryoelectron Microscopy

Although some proteins readily crystallize, obtaining crystals of others — particularly large multisubunit proteins and membrane-associated proteins — requires a time-consuming, often robot-

assisted trial-and-error effort to find just the right conditions, if they can be found at all. (Growing crystals suitable for structural studies is as much an art as a science.) There are several alternative ways to determine the structures of such difficult-to-crystallize proteins. One is cryoelectron microscopy (Figure 3-49). In this technique, a dilute protein sample in an aqueous solution is applied in a thin layer to an electron microscope sample holder (a "grid") and rapidly frozen in liquid helium to preserve its structure. It is then examined in the frozen, hydrated state in a cryoelectron microscope. Images of the protein are recorded on a very sensitive camera using a low dose of electrons to prevent radiation-induced damage to the structure. Since the individual proteins are in different orientations in the frozen sample, sophisticated computer algorithms analyze the images to sort them into groups with the same orientation. The average image of each orientation is calculated from images of the thousands of different molecules in each group, and then the computer assembles the average images, each of which show views of the protein from different orientations, to reconstruct the protein's structure in three dimensions. Recent advances in this technology have produced structures in which the polypeptide backbone and amino acid side chains can be discerned with resolutions reported to be as high as $\sim$2 Å and for many structures greater than 4 Å. These structures help provide insight into the mechanisms underlying the protein's function. The use of cryoelectron microscopy and other types of electron microscopy for visualizing cell structures is discussed in Chapter 4.

EXPERIMENTAL FIGURE 3-49 Cryoelectron microscopy analysis of the structure of the human mitochondrial ribosome. The mitochondrion is a complex, multifunctional intracellular organelle best known for its ability to synthesize the energy carrier ATP (see Chapter 12). Human mitochondria can synthesize proteins encoded by mitochondrial DNA using large (1.7 MDa), multiprotein (at least 78) and multi-RNA complexes called *mitochondrial ribosomes* that differ somewhat from cytoplasmic ribosomes. (a) Cryoelectron micrograph of isolated human mitochondrial ribosomes. The low contrast between the ribosomes and the buffer solution makes it difficult to clearly see individual, frozen ribosome particles, which are oriented randomly in the image. (b) Automated image processing of 323,292 individual particles permits their grouping into classes based on orientation and averaging of the images within each class to generate clearer images of the ribosome. (c) Additional computational analysis generates distinct structures, each based on tens of thousands of individual particles (the number of particles analyzed for each

structure in thousands [K] is shown beneath each). The structures enclosed in boxes were selected for additional analysis, which produced the two very similar models shown in (d) containing virtually identical large subunits. (e) Color-coded, low-resolution model of the electron density of the large (blue) and small (yellow) subunits. The conformational heterogeneity of the small subunit prevented the determination of its high-resolution structure from the data shown here. (f) High-magnification view of the experimentally determined electron density (meshwork) from a very small portion of one protein within the large subunit. This view illustrates how the electron density is used to build the superimposed molecular model of polypeptide chains. The side chains of proline (Pro), phenylalanine (Phe), valine (Val), and tyrosine (Tyr) residues are easily seen and demonstrate the power of cryoelectron microscopy to determine protein structures at very high resolutions. (g) Model of the 48 protein subunits (different colors) in the large subunit determined at 3.4 Å resolution.

NMR Spectroscopy

The three-dimensional structures of small proteins containing as many as 200 amino acids can be studied routinely with nuclear magnetic resonance (NMR) spectroscopy, and specialized approaches can be used to extend the size range to somewhat larger proteins. In this technique, a concentrated protein solution is placed in a magnetic field, and the effects of different radio frequencies on the nuclear spin states of different atoms are measured. The spin state of any atom is influenced by neighboring atoms in adjacent residues, with closely spaced residues having a greater effect than distant residues. From the magnitude of the effect, the distances

between residues can be calculated by a triangulation-like process; these distances are then used to generate a model of the three-dimensional structure of the protein. An important distinction between x-ray crystallography and NMR spectroscopy is that the former method directly determines the locations of the atoms, while the latter directly determines the distances between the atoms, from which the structure is deduced.

Although NMR does not require the crystallization of a protein — a definite advantage — this technique is usually limited to proteins smaller than about 80 kDa (although new techniques permit analysis of the dynamics in much larger proteins). The precision of an NMR structure can be as high as ~2 Å. NMR analysis can provide information about the ability of a protein to adopt a set of closely related, but not exactly identical, conformations and to move between those conformations (protein dynamics). This is a common feature of proteins, which are not absolutely rigid structures, but can "breathe" or exhibit slight variations in the relative positions of their constituent atoms. In some cases, these variations can have functional significance; for example, they may influence how proteins bind to one another. NMR structural analysis has been particularly useful in studying isolated protein domains, which can often be obtained as stable structures and tend to be small enough for this technique. To date, there are more than 13,000 NMR-determined structures available in the Protein Data Bank.

Another powerful approach to studying protein dynamics and protein-protein interactions is hydrogen/deuterium exchange mass spectrometry (HXMS). When a protein is placed in a deuterated water (D_2O) solution, the rate at which deuterium is exchanged for hydrogen in the amides in the peptide bonds depends on the accessibility of an amide to the solvent. Those amides exposed on the protein's surface are highly accessible and exhibit rapid proton/deuterium exchange. Those amides buried in the center of the protein or in a protein-to-protein interface, as well as those participating in hydrogen bonds with other parts of the protein, exhibit slower proton/deuterium exchange rates. A change in protein conformation or binding to other molecules has the potential to alter the rate of hydrogen/deuterium exchange of one or more amides of a protein. MS analysis permits a hypersensitive assay of such conformational changes, allowing the identification of those parts of the protein that directly bind to other molecules or undergo such conformational changes.

KEY CONCEPTS OF SECTION 3.5

Purifying, Detecting, and Characterizing Proteins

- Proteins can be separated from other cell components and from one another on the basis of differences in their physical and chemical properties.
- Centrifugation separates proteins on the basis of their rates of sedimentation, which are influenced by their masses and shapes (see Figure 3-40).
- Electrophoresis separates proteins on the basis of their rates of movement in an applied electric field. SDS-polyacrylamide gel electrophoresis (SDS-PAGE) can resolve polypeptide chains differing in molecular weight by 10 percent or less (see Figure 3-

41). Two-dimensional gel electrophoresis provides additional resolution by separating proteins first by charge (first dimension) and then by mass (second dimension).

- Liquid chromatography separates proteins on the basis of their rates of movement through a column packed with spherical beads. Proteins differing in mass are resolved on gel filtration columns: those differing in charge using ion-exchange columns and those differing in ligand-binding properties using affinity columns (see Figure 3-43).
- Various assays are used to detect and quantify proteins. Some assays use a light-producing reaction to generate a readily detected signal. Other assays produce an amplified colored signal with enzymes and chromogenic substrates.
- Antibodies are powerful reagents used to detect, quantify, and isolate proteins.
- Immunoblotting, also called *Western blotting*, is a frequently used method to study specific proteins that exploits the high specificity and sensitivity of protein detection by antibodies and the high-resolution separation of proteins by SDS-PAGE (see Figure 3-44).
- Immunoprecipitation, often abbreviated as *IP*, permits the separation of a protein of interest from other proteins in a complex mixture using antibodies specific for the protein of interest. The antibodies are used to precipitate their target protein out of solution for subsequent analysis. Molecules tightly bound to the target protein can precipitate with it (co-immunoprecipitation).
- Isotopes, both radioactive and nonradioactive, play a key role in the study of proteins and other biomolecules. They can be incorporated into molecules without changing the chemical composition of the molecule or as add-on tags. They can be used to help detect the synthesis, location, processing, and stability of proteins.
- Autoradiography is a technique for detecting radioactively labeled molecules in cells, tissues, or electrophoretic gels using two-dimensional detectors (photographic emulsion or electronic detectors).
- Pulse-chase experiments can determine the intracellular fate of proteins and other metabolites (see Figure 3-45).
- Mass spectrometry is a very sensitive and highly precise method of detecting, identifying, and characterizing proteins and peptides.
- Three-dimensional structures of proteins are obtained by x-ray crystallography, cryoelectron microscopy, and NMR spectroscopy. X-ray crystallography provides the most detailed structures but requires protein crystallization. Cryoelectron microscopy is most useful for large protein complexes, which are difficult to crystallize. Only relatively small proteins are amenable to NMR three-dimensional structural analysis.

3.6 Proteomics

For most of the twentieth century, the study of proteins was restricted primarily to the analysis of individual proteins. For example, one would study an enzyme by determining its enzymatic activity (its substrates, products, rate of reaction, requirement for cofactors, pH dependence, etc.), its structure, and its mechanism of action. In some cases, the relationships between a few enzymes that participate in a metabolic pathway might also be studied. On a broader scale, the localization and activity of an enzyme would be examined in the context of a cell or tissue. The effects of mutations, diseases, or drugs on the expression and activity of the enzyme might also be the subject of investigation. This multipronged approach provided deep insight into the function and mechanisms of action of individual proteins or small numbers of interacting proteins. However, studying proteins one at a time does not provide a global picture of what is happening for the collection of all proteins — the **proteome** — of an organelle, cell, tissue, or entire organism.

Proteomics Is the Study of All or a Large Subset of Proteins in a Biological System

The advent of genomics (sequencing of genomic DNA and its associated technologies, e.g., simultaneous analysis of the levels of all mRNAs in cells and tissues) clearly showed that a global, or systems, approach to biology could provide unique and highly valuable insights. Many scientists recognized that a global analysis of the proteins in biological systems had the potential for equally valuable contributions to our understanding. Thus a new field was born — **proteomics**. Proteomics is the systematic study of the amounts, modifications, interactions, localization, and functions of all or subsets of proteins at the whole-organism, tissue, cellular, and subcellular levels.

A number of broad questions are addressed in proteomic studies:

- In a given sample (whole organism, tissue, cell, subcellular compartment), what fraction of the whole proteome is expressed (i.e., which proteins are present)?
- Of those proteins present in the sample, what are their relative abundances? The relative amounts of particular proteins provide a measure of the influence those proteins have on the behavior or function of a cell and how a cell might interact with its environment. Although the levels of mRNAs clearly influence the amounts of the corresponding protein made (see Chapter 8), there is relatively poor correlation between the relative amounts of proteins and corresponding mRNA abundance. This is because protein levels are also influenced by translation efficiency and regulation, post-translational modifications, and rates of protein degradation (see Chapter 9). Consequently, one

cannot always predict the level of a protein in a cell from its mRNA abundance. Thus even though there are rapid, efficient, and cost effective methods to measure mRNA levels of many genes in samples, including single cells (see Chapter 6), direct measurement of protein levels is necessary to understand the mechanisms that control protein abundance and the roles of proteins in cellular functions.

- What are the relative amounts of the different splice forms and chemically modified forms (e.g., phosphorylated, methylated, fatty acylated) of the proteins?
- Which proteins are present in large multiprotein complexes, and which proteins are in each complex? What are the functions of these complexes, and how do they interact?
- When the state (e.g., growth rate, stage of cell cycle, differentiation, stress level) of a cell changes, do the proteins in the cell, or those secreted from the cell, change in a characteristic (*fingerprint*-like) pattern? Which proteins change, and how (relative amounts, modifications, splice forms, etc.)? [Answering these questions requires a form of *protein expression profiling* that complements the *transcriptional (mRNA) profiling* discussed in Chapter 8.]
- Can such fingerprint-like changes be used for diagnostic purposes? For example, do certain cancers or heart disease cause characteristic changes in blood proteins or do certain patterns in the levels of proteins predict an increased risk for disease? Can the proteomic fingerprint help determine if a given cancer is resistant or sensitive to a particular chemotherapeutic drug? [Proteomic fingerprints can also be the

starting point for studies of the mechanisms underlying the change of state. Proteins (and other biomolecules) that show changes that are diagnostic of a particular state are called *biomarkers*.]

- Which proteins in a cell are in close proximity to one another? Which are joined in multiprotein complexes, stably reside close to one another as independent proteins (e.g., in the matrix or inner membrane space of the mitochondrion; see Chapter 12), or transiently come together due to some signaling process, such as when a hormone induces changes in the cell's state?
- Can changes in the proteome help define targets for drugs or suggest mechanisms by which a drug might induce toxic side effects? If so, it might be possible to engineer modified versions of the drug with fewer side effects. Proteomics methods can also be used to identify cellular proteins that bind to small-molecule drugs and thus identify potential protein targets of the drugs.
- Proteins undergo post-translational changes including chemical modifications, alterations in stability, interactions with other proteins, and changes in intracellular localization. What post-translational changes in proteins arise from changes (mutations, copy number variants) to genes in the genome? Some of these post-translational changes in proteins (e.g., phosphorylation or dephosphorylation) can only be identified by direct examination of the proteins themselves.

These are just a few of the questions that can be addressed using proteomics. The methods used to answer these questions are as

diverse as the questions themselves, and their numbers are growing rapidly.

Advanced Techniques in Mass Spectrometry Are Critical to Proteomic Analysis

Advances in proteomics technologies (e.g., mass spectrometry) profoundly affect the types of questions that can be practically studied. A widely used method to identify the protein components in a complex biological sample is *high-throughput LC-MS/MS*. Figure 3-50 outlines the general LC-MS/MS approach. In this approach, a complex mixture of proteins is digested with a protease, and the myriad resulting peptides are fractionated by LC into multiple, less complex fractions. After exiting the LC column, the fractions are continuously subjected to electrospray ionization and injection into a tandem mass spectrometer. The first fraction from the LC column enters the mass spectrometer and the multiple peptides (orange and teal) in that fraction are trapped as ions in the first MS analyzer. One of these (orange) is selected based on its mass for fragmentation and then its fragments are characterized in the second MS analyzer to determine its sequence. This process of selection, fragmentation, and sequencing is repeated sequentially for the other peptides in the first fraction that remains trapped in the first MS analyzer. Each of the subsequent fractions that enter the mass spectrometer are then

sequentially subjected to the same series of multiple cycles of MS/MS (peptide selection, fragmentation, sequencing) until the sequences of many of the peptides in the original mixture of peptides have been determined. Then, computations methods are used to identify, from the large collection of sequenced short peptides and protein databases, virtually all the proteins in the original biological sample. Using just a few 10's of μg of protein per sample, a substantial fraction of the actively expressed proteome in cells or tissues can be detected and quantified by this method, amounting to 10,000–12,000 proteins. At present, as many as 5000–7000 distinct proteins can be detected from a sample of as little as 1–2 μg of protein. This much sample can be obtained from 10,000–150,000 cells, depending on the types of cells used and losses of material during sample preparation. Efforts are under way to increase the sensitivity of the method so that eventually one might be able to analyze the entire proteome of an individual cell.

EXPERIMENTAL FIGURE 3-50 LC-MS/MS is used to identify the proteins in a complex biological sample. A complex mixture of proteins in a biological sample (e.g., an isolated preparation of Golgi organelles) is digested with a protease. The mixture of resulting peptides is fractionated by liquid chromatography (LC) into multiple, less complex, fractions, which are slowly but continuously injected by electrospray ionization into a tandem mass spectrometer. From the peptides in each fraction trapped in the first MS analyzer (orange and teal), one (orange) is selected for fragmentation and sequencing, and the remaining peptides in that fraction are sequentially fragmented and sequenced. The subsequent fractions to enter the mass spectrometer are then sequentially subjected to the same process of multiple cycles of MS/MS until the masses and sequences of many of the peptides in the original complex mixture have been determined and used to identify by computation the proteins in the original biological sample through comparison with protein databases.

An example of the use of LC-MS/MS to identify many of the proteins in each organelle is seen in Figure 3-51. Cells from murine (mouse)

liver tissue were mechanically broken to release the organelles, and the organelles were partially separated by density-gradient centrifugation. The locations of the organelles in the gradient were determined using immunoblotting with antibodies that recognized previously identified, organelle-specific proteins. Fractions from the gradient were then subjected to LC-MS/MS to identify the proteins in each fraction, and the distributions in the gradient of many individual proteins were compared with the distributions of the organelles. This strategy permitted the assignment of many individual proteins to one or more organelles (organelle proteome profiling). More recently, a combination of organelle purification, MS, biochemical localization, and computational methods has been used to show that at least a thousand distinct proteins are localized in the mitochondria of humans and mice.

EXPERIMENTAL FIGURE 3-51 Density-gradient centrifugation and LC-MS/MS can be used to identify many of the proteins in organelles. (a) The cells in liver tissue were mechanically broken to release the organelles, and the organelles were partially separated by density-gradient centrifugation. The locations of the organelles — which were spread out through the gradient and somewhat overlapped with one another — were determined using immunoblotting with antibodies that recognized previously identified, organelle-specific proteins. Fractions from the gradient were subjected to proteolysis and LC-MS/MS to identify the peptides, and hence the proteins, in each fraction. Comparisons with the locations of the organelles in the gradient (called *protein correlation profiling*) permitted assignment of many individual proteins to one or more organelles (organelle proteome identification). (b) The hierarchical breakdown of data derived from the procedures in part (a). Note that not all proteins identified could be assigned to organelles and that some proteins were assigned to more than one organelle.

[Data from L. J. Foster et al., 2006, *Cell* **125**:187–199.]

A powerful method to identify proteins that are spatially near to one another, either in direct physical contact or simply co-localized in the cell, is enzyme-catalyzed, proximity-dependent labeling coupled with mass spectrometry. In this method, cells are engineered with recombinant DNA to express a protein of interest that has fused to it a specialized enzyme. When the cells are exposed to the substrates of the enzyme, the enzyme converts a substrate to a highly reactive chemical that can covalently label proteins in the immediate vicinity (approximately 10–20 nm) of the fused protein of interest. One must be careful to show that the fusion of the enzyme to the protein does not disrupt its normal location and binding partners in the cell. The most common substrate used for proximity-dependent labeling contains the small molecule biotin, which is activated by the enzyme and then covalently attaches to nearby proteins. After the

labeling reaction in the living cells, all proteins can be extracted from the cells and the biotinylated proteins — those near the fused protein of interest — separated by affinity chromatography (see Figure 3-43c) using a column with beads containing instead of an antibody the protein streptavidin that binds biotin very tightly. The identities of the isolated, biotinylated proteins are then determined by proteolysis and LC-MS/MS. This approach has been used to identify 495 proteins that reside in the subcompartment of mitochondria called the *matrix* (Chapter 12) and the proteins in other subcompartments in cells that are difficult to purify biochemically. Additional experiments are required to determine the functional relationships of proteins shown to be in close proximity to each other.

Proteomics methods combined with molecular genetics methods are currently being used to identify all the protein complexes in eukaryotic cells. For example, in the yeast *Saccharomyces cerevisiae*, approximately 500 complexes, with an average of 4.9 distinct proteins per complex, have been identified. These complexes, in turn, are involved in at least 400 complex-to-complex interactions. Such systematic proteomic studies are providing new insights into the organization of proteins within cells and into how proteins work together to permit cells to live and function.

Phosphoproteomics, the identification and quantification of phosphorylation sites on the proteins in a complex mixture, is

playing a growing role in the analysis of cell metabolism and regulation. As we have already learned, the reversible phosphorylation of proteins by kinases and phosphatases is a key mechanism for regulating proteins in cells. Phosphoproteomics permits the simultaneous determination of the phosphorylation states of many proteins and thus provides an important tool for analyzing complex cellular regulatory networks. Only a fraction — in some cases, only a small fraction — of a particular protein might be phosphorylated. Thus phosphoproteomic analysis can require 50–100 times more initial cell or tissue sample material (from about 2.5 to more than 20 mg of total cellular protein per sample) than does standard proteomic analysis. As a consequence, investigators usually use affinity chromatography methods with either metal-containing (e.g., Fe^{3+} or TiO_2) or antibody-containing columns to separate phosphopeptides from nonphosphorylated peptides (phosphopeptide enrichment) prior to subjecting the phosphopeptides to LC-MS/MS analysis.

KEY CONCEPTS OF SECTION 3.6

Proteomics

- Proteomics is the systematic study of the amounts (and changes in the amounts), modifications, interactions, localization, and functions of all or subsets of all proteins in biological systems at the whole-organism, tissue, cellular, and subcellular levels.
- Proteomics provides insights into the fundamental organization of proteins within cells and how that organization is influenced by the state of the cells (e.g., differentiation into distinct cell types; responses to stress, disease, and drugs).
- A wide variety of methods are used for proteomic analyses, including two-dimensional gel electrophoresis, density-gradient centrifugation, and mass spectrometry

(particularly LC-MS/MS).

- Proteomics has helped begin to identify the proteomes of organelles ("organelle proteome profiling") as well as the organization of individual proteins into multiprotein complexes (see Figure 3-51).
- Phosphoproteomics is a specialized application of proteomics that identifies the collection of phosphorylated proteins (phosphoproteome) in cells and characterizes how the level of phosphorylation of these proteins varies as the state of the cells changes.

Review the Concepts

1. The three-dimensional structure of a protein is determined by its primary, secondary, and tertiary structures. Define the *primary, secondary*, and *tertiary structures*. What are some of the common secondary structures? What are the forces that hold together the secondary and tertiary structures?

2. Proper folding of proteins is essential for their biological activity. In general, the functional conformation of a protein is the conformation with lowest energy. This means that if an unfolded protein is allowed to reach equilibrium, it should assemble automatically into its native, functioning folded state. Why then is there a need for molecular chaperones and chaperonins in cells? What different roles do molecular chaperones and chaperonins play in the folding of proteins?
3. Enzymes catalyze chemical reactions. What constitutes the active site of an enzyme? What are the turnover number, the Michaelis constant (K_{m}), and the maximal velocity (V_{max}) of an enzyme? The turnover number for carbonic anhydrase is 5×10^5 molecules per second. This is a "rate constant," but not a "rate." What is the difference? By what concentration would you multiply this rate constant in order to determine an actual rate of product formation (V)? Under what circumstances would this rate become equal to the maximal velocity (V_{max}) of the enzyme?
4. The following reaction-coordinate diagram charts the energy of a substrate molecule (S) as it passes through a transition state ($X^{\ddagger}$) on its way to becoming a stable product (P) alone or in the presence of one of two different enzymes (E1 and E2). How does the addition of either enzyme affect the change in Gibbs free energy (ΔG) for the reaction? Which of the two enzymes binds with greater affinity to the substrate? Which enzyme better stabilizes

the transition state? Which enzyme functions as a better catalyst?

5. A healthy immune system can raise antibodies that recognize and bind with high affinity to almost any stable molecule. The molecule to which an antibody binds is known as an *antigen*. Antibodies have been exploited by enterprising scientists to generate valuable tools for research, diagnosis, and therapy. One clever application is the generation of antibodies that function like enzymes to catalyze complicated chemical reactions. If you wished to produce such a catalytic antibody, what would you suggest using as the antigen? Should it be the substrate of the reaction? The product? Something else?

6. Proteins are degraded in cells. What is ubiquitin, and what role does it play in tagging proteins for degradation? What is the role of proteasomes in protein degradation? How might proteasome inhibitors serve as chemotherapeutic (cancer-treating) agents?
7. The function of proteins can be regulated in a number of ways. What is cooperativity, and how does it influence protein function? Describe how protein phosphorylation and proteolytic cleavage can modulate protein function.
8. A number of techniques can separate proteins on the basis of their differences in mass. Describe the use of two of these techniques, centrifugation and gel electrophoresis. The blood proteins transferrin (MW 76 kDa) and lysozyme (MW 15 kDa) can be separated by rate-zonal centrifugation or SDS-polyacrylamide gel electrophoresis. Which of the two proteins will sediment faster during centrifugation? Which will migrate faster during electrophoresis?
9. Liquid chromatography is an analytical method used to separate proteins. Describe the principles for separating proteins by gel filtration, ion-exchange, and affinity chromatography.
10. Various methods have been developed for detecting proteins. Describe how radioisotopes and autoradiography can be used for labeling and detecting proteins. How does Western blotting detect proteins?
11. Physical methods are often used to determine protein conformation. Describe how x-ray crystallography, cryoelectron microscopy, and NMR spectroscopy can be

used to determine the shapes of proteins. What are the advantages and disadvantages of each method? Which is better for small proteins? Large proteins? Huge macromolecular assemblies?

12. Mass spectrometry is a powerful tool in proteomics. What are the four key features of a mass spectrometer? Describe briefly how MALDI and two-dimensional polyacrylamide gel electrophoresis could be used to identify a protein expressed in cancer cells but not in normal healthy cells.

CHAPTER 4

Culturing and Visualizing Cells

Torsten Wittman, University of California, San Francisco.

Fluorescence microscopy showing the locations of DNA (green), microtubules (yellow), and microfilaments (purple) in two cultured cells. The cells were chemically fixed and then rendered permeable to antibodies using a gentle detergent. Microtubules were stained with

an antibody to tubulin; microfilaments were stained with a labeled toxin, phalloidin, that binds selectively to F-actin; and DNA was visualized with a DNA-binding dye.

OUTLINE

4.1 Growing and Studying Cells in Culture
4.2 Light Microscopy: Exploring Cell Structure and Visualizing Proteins Within Cells
4.3 Electron Microscopy: High-Resolution Imaging
4.4 Isolation of Cell Organelles

It is difficult to believe that just 200 years ago it was not yet appreciated that all living things are made of cells. In 1655, Robert Hooke used a primitive microscope to examine a piece of cork and saw an orderly arrangement of rectangles — the walls of the dead plant cells — that reminded him of monks' cells in a monastery, so he coined the term *cell*. Shortly after this, Antoni van Leeuwenhoek's observations of the microorganisms he saw in his simple microscope became the first description of live cells. Two hundred years later, Matthias Schleiden and Theodore Schwann proposed that cells constitute the fundamental unit of life in plants, animals, and single-celled organisms. Collectively, these discoveries were some of the greatest in biology and posed the question of how cells are organized and function.

Even today, many technical constraints hamper studies of cells in intact animals and plants. One alternative is the use of intact organs that are removed from animals and treated to maintain their physiological integrity and function. However, the organization of

organs, even isolated ones, is sufficiently complex to pose numerous problems for research. Thus molecular cell biologists often conduct experimental studies on cells isolated from an organism. In Section 4.1, we learn how to maintain and grow diverse cell types and how to isolate specific types of cells from complex mixtures.

In many cases, isolated cells can be maintained in the laboratory under conditions that permit their survival and growth, a procedure known as *culturing*. Cultured cells have several advantages over intact organisms for cell biology research. Cells of a single specific type can be grown in culture, experimental conditions can be better controlled, and in many cases a single cell can be readily grown into a colony of many identical cells. The resulting strain of cells, which are genetically homogeneous, is called a **clone**. However, cultured cells are not in their native setting, so researchers are now growing and examining cells in three-dimensional environments to more closely mimic their situation in an animal.

Discoveries about cellular organization have been intimately tied to developments in microscopy. This is as true today as it was 400 years ago. Light microscopy initially revealed the beautiful internal organization of cells, and today highly sophisticated microscopes are continually being improved to probe deeper and deeper into the molecular mechanisms by which cells function. In Section 4.2, we discuss light microscopy and the long-standing but still valuable techniques that are in use today, and then examine several clever

methods that have been developed more recently, culminating with the newest, cutting-edge technologies. A major advance came in the 1960s and 1970s with the development of immunofluorescence microscopy, which allows the localization of specific proteins within fixed cells, thus providing a static image of their location, as illustrated in the chapter-opening figure. Such studies led to the important understanding that the membranes and interior spaces of each type of organelle contain a distinctive group of proteins that are necessary for the organelle to carry out its unique functions. Another major advance came in the mid-1990s with the simple idea of expressing *chimeric proteins* — consisting of a protein of interest covalently linked to a naturally fluorescent protein — which has enabled biologists to visualize movements of individual proteins in live cells. Suddenly, the dynamic nature of cells could be appreciated. This has dramatically changed our view of cells when we were limited to only static images. Microscopes with higher sensitivity coupled with methods to enhance resolution now allow investigators to gain more information about the detailed structure and dynamics of cells. The development of fluorescence techniques also led to the development of methods to monitor protein-protein interactions in live cells, as well as a myriad of other sophisticated molecular technologies, some of which we discuss in this section. For decades, light microscopy was constrained by the resolution of the light microscope — to about 200 nm — due to the limitations imposed by the wavelength of visible light. We discuss methods that

have been developed over the last few years to beat this resolution barrier with the development of *super-resolution microscopy*.

Despite the amazing developments in light microscopy, visible light still provides too low a resolution to examine cells in fine, ultrastructural detail. The electron microscope gives a much higher resolution, but the technology generally requires that the cell be fixed and sectioned, and therefore all cell movements are frozen in time. Electron microscopy also allows investigators to examine the structure of macromolecular complexes or single macromolecules. In Section 4.3, we outline the various approaches for preparing specimens for observation in the electron microscope and describe the types of information that can be derived from them.

Light and electron microscopy revealed that all eukaryotic cells contain a similar repertoire of membrane-limited compartments termed *organelles*. In parallel with the developments in microscopy, subcellular fractionation methods were developed that have enabled cell biologists to isolate individual organelles to a high degree of purity. These techniques, detailed in Section 4.4, continue to provide important information about the protein composition and biochemical function of organelles.

4.1 Growing and Studying Cells in Culture

The study of cells is greatly facilitated by growing them in culture, so that they can be examined by microscopy and subjected to specific treatments under controlled conditions. It is generally quite easy to grow unicellular bacteria, fungi, or protists, for example, by placing them in a rich medium that supports their growth. However, animal cells come from multicellular organisms, which makes it more difficult to culture single cells or small groups of cells. In this section, we discuss how animal cells are grown in culture and how different cell types can be purified for study.

Culture of Animal Cells Requires Nutrient-Rich Media and Special Solid Surfaces

To permit the survival and normal function of cultured tissues or cells, the temperature, pH, ionic strength, and access to essential nutrients must simulate as closely as possible the conditions within an intact organism. Isolated animal cells are typically placed in a nutrient-rich liquid, called the *culture medium*, within specially coated plastic dishes or flasks. The cultures are kept in incubators in which the temperature, atmosphere, and humidity can be

controlled. To reduce the chances of bacterial or fungal contamination, antibiotics are often added to the culture medium. To further guard against contamination, investigators usually transfer cells between dishes, add reagents to the culture medium, and otherwise manipulate the specimens within special sterile cabinets containing circulating air that is filtered to remove microorganisms and other airborne contaminants.

Media for culturing animal cells must supply the nine amino acids (phenylalanine, valine, threonine, tryptophan, isoleucine, methionine, leucine, lysine, and histidine) that cannot be synthesized by adult vertebrate animal cells. In addition, most cultured cells require three other amino acids (cysteine, tyrosine, and arginine) that are synthesized only by specialized cells in intact animals, as well as glutamine, which serves as a nitrogen source. The other necessary components of a medium for culturing animal cells are vitamins, various salts, fatty acids, glucose, and serum — the fluid remaining after the noncellular part of blood (plasma) has been allowed to clot. Serum contains various protein factors that are needed for the proliferation of mammalian cells in culture, including the polypeptide hormone insulin; transferrin, which supplies iron in a bioaccessible form; and numerous growth factors. In addition, certain cell types require specialized protein growth factors not present in serum. For instance, progenitors of red blood cells require erythropoietin, and T lymphocytes require interleukin 2 (see Chapter 16). A few mammalian cell types can be grown in a chemically defined, serum-free medium containing amino acids,

glucose, vitamins, and salts plus certain trace minerals, specific protein growth factors, and other components.

Unlike bacterial and yeast cells, which can be grown in suspension, most animal cell types will grow only when attached to a solid surface. This requirement highlights the importance of the cell-surface proteins, called **cell-adhesion molecules (CAMs)**, that cells use to bind to adjacent cells and to components of the extracellular matrix such as collagen, laminin, or fibronectin (see Chapter 20). The solid growth surface (usually glass or plastic) is either pre-coated with these extracellular-matrix proteins, or they come from the serum or are secreted by the cells in culture. A single cell cultured on a glass or plastic dish proliferates to form a visible mass, or *colony*, containing thousands of genetically identical cells in 4 to 14 days, depending on the growth rate. Although most normal animal cells require a surface to grow on, some specialized blood cells, and especially tumor cells, can be grown in suspension as single cells.

Primary Cell Cultures and Cell Strains Have a Finite Life Span

Primary cells are cells isolated directly from tissues. Normal animal tissues (e.g., skin, kidney, liver) or whole embryos are commonly used to establish *primary cell cultures*. To prepare individual tissue

cells for a primary culture, the cell-cell and cell-matrix interactions must be broken. To do so, tissue fragments are treated with a combination of a protease (e.g., trypsin, the collagen-hydrolyzing enzyme collagenase, or both) and a divalent cation chelator (e.g., EDTA) that depletes the medium of free calcium (Ca^{2+}). Many CAMs require calcium and are thus inactivated when calcium is removed; other CAMs that are not calcium dependent need to be cleaved by a protease for the cells to separate. The released cells are then placed in a nutrient-rich, serum-supplemented medium in dishes, where they can adhere to the surface and to one another. The same protease-chelator solution is used to remove adherent cells from a culture dish for biochemical studies or subculturing (transfer to another dish).

Fibroblasts are the predominant cells in connective tissue and normally produce extracellular-matrix components, such as collagen, that bind to CAMs, thereby anchoring cells to a surface. In culture, fibroblasts usually divide more rapidly than other cells from a tissue, eventually becoming the predominant cell type in a primary culture unless special precautions are taken to remove them when isolating other types of cells.

When cells removed from an embryo or an adult animal are cultured, most of the adherent cells will divide a finite number of times and then cease growing (a phenomenon called *cell senescence*). For instance, human fetal fibroblasts divide about 50 times before

they cease growth. Starting with 10^6 cells, 50 doublings has the potential to produce $10^6 \times 2^{50}$, or more than 10^{20}, cells, whose weight would be equivalent to that of about a thousand people. Normally, only a very small fraction of these cells are used in any one experiment. Thus even though its lifetime is limited, a single culture, if carefully maintained, can be studied through many cell generations. Such a lineage of cells originating from one initial primary culture is called a **cell strain**.

One important exception to the finite life span of normal cells is the *embryonic stem cell*, which, as its name implies, is derived from an embryo and will divide and give rise to all tissues during development. As we discuss in Chapter 22, embryonic stem cells can be cultured indefinitely under the appropriate conditions.

Research with cell strains is simplified by our ability to freeze them and successfully thaw them at a later time for experimental analysis. Cell strains can be frozen in a state of suspended animation and stored for extended periods at liquid nitrogen temperature, provided that a preservative that prevents the formation of damaging ice crystals is used. Although not all cells survive thawing, many do survive and resume growth.

Transformed Cells Can Grow Indefinitely in Culture

To be able to clone individual cells, modify cell behavior, or select mutants, biologists often want to maintain cell cultures for many more than 50 doublings. Such prolonged growth is exhibited by cells derived from some tumors. In addition, rare cells in a population of primary cells may undergo spontaneous oncogenic mutations, leading to *oncogenic transformation* (see Chapter 25). Such cells, said to be oncogenically transformed, or simply *transformed*, are able to grow indefinitely. A culture of cells with an indefinite life span is considered immortal and is called a **cell line**.

The HeLa cell line, the first human cell line established, was originally obtained in 1952 from a malignant tumor (carcinoma) of the uterine cervix and is still used extensively today. The cells were obtained from Henrietta Lacks without her consent, which has raised ethical issues concerning ownership of biological materials. Many other human cell lines are derived from cancers, and biologists have rendered others immortal by transforming them to express oncogenes.

Regardless of their source, cells in immortal lines often have chromosomes with abnormal DNA sequences. In addition, the number of chromosomes in such cells is usually greater than that in the normal cell from which they arose, and the chromosome number changes as the cells continue to divide in culture. A noteworthy exception is a human cell line of hematopoietic origin that is haploid for all chromosomes except chromosome 8. Since

inactivation of one of the two copies of a gene in a diploid cell generally does not generate a phenotype, a line with a single copy of most genes is very useful for genetic analysis, making possible the types of genetic screens employed in model organisms (see Chapter 6). Cells with an abnormal number of chromosomes are said to be *aneuploid*.

Flow Cytometry Separates Different Cell Types

Some cell types differ sufficiently in density that they can be separated on the basis of this physical property. White blood cells (leukocytes) and red blood cells (erythrocytes), for instance, have very different densities because erythrocytes have no nucleus; thus these cells can be separated by equilibrium density-gradient centrifugation (described in Section 4.4). Most cell types cannot be differentiated so easily, so other techniques, such as flow cytometry, must be used to separate them.

To separate one type of cell from a complex mixture, it is necessary to have some way to mark and then sort out the desired cells. As we will see below, it is possible to mark cells by expressing a fluorescent protein in them, but if only a few cells in the population express the protein, how can we sort them from the nonfluorescent ones? The cells can be analyzed in a *flow cytometer*. This machine flows cells

past a laser beam that measures the light that they scatter and the fluorescence that they emit; thus it can quantify the cells expressing the fluorescent protein in a mixture. A **fluorescence-activated cell sorter (FACS)**, which is based on flow cytometry, can both analyze the cells and select the few fluorescent cells from thousands of others and sort them into a separate culture dish (Figure 4-1). To achieve this, the cells are mixed with a buffer and forced through a vibrating nozzle to generate tiny droplets. The concentration of cells is adjusted so that most of the droplets do not contain cells, and the ones that do contain only one. Just before the nozzle, the stream of cells passes through a laser beam so that the presence and size of a cell can be recorded from the scattered light using one detector, and the amount of fluorescent light emitted can be quantified using a second, fluorescent light detector. If a cell is present in a droplet, the droplet is given a negative electric charge as it emerges from the nozzle. The stream of droplets then passes through two plates that generate an electric field proportional to the fluorescence detected from the cell in the droplet. This field generates a force that moves charged droplets out of the stream of uncharged droplets and into a collection tube. Since the amount of force applied is proportional to the fluorescence emitted by the cell in the droplet, cells with different levels of fluorescence can be collected. Having been sorted from other cells, the selected cells can be grown in culture.

FIGURE 4-1 A fluorescence-activated cell sorter (FACS) separates cells having different levels of fluorescence. Step 1: A concentrated suspension of labeled cells is mixed with a buffer so that the cells pass single file through a laser light beam. Step 2: Both the fluorescent light emitted and the light scattered by each cell are measured; from measurements of the scattered light, the size and shape of the cell can be determined. Step 3: The suspension is then forced through a nozzle, which forms tiny droplets containing at most a single cell. At the time of formation at the nozzle tip, each droplet containing a cell is given a negative electric charge proportional to the fluorescence of that cell determined from the earlier measurement. Step 4: Droplets now pass through an electric field, so that those with no charge are discarded, whereas those with different electric charges are separated and collected. Because it takes only milliseconds to sort each droplet, as many as 10 million cells per hour can pass through the machine.

The FACS procedure is commonly used to purify different types of white blood cells, each of which bears on its surface one or more distinctive proteins and so will bind monoclonal antibodies specific for its proteins. If a cell mixture is incubated with a fluorescent dye linked to the antibody to a specific cell-surface protein, only the desired cells will be fluorescent. Only the T cells of the immune system, for instance, have both CD3 and Thy1 proteins on their surfaces. The presence of these surface proteins allows T cells to be separated easily from other types of blood cells or spleen cells (Figure 4-2).

EXPERIMENTAL FIGURE 4-2 FACS separates T cells with bound fluorescence-tagged antibodies to two cell-surface proteins from other white blood cells. Spleen cells from a mouse were treated with a red fluorescent monoclonal antibody specific for the CD3 cell-surface protein and with a green fluorescent monoclonal antibody specific for a second cell-surface protein, Thy1. As the cells passed through a FACS, the intensity of the green and red fluorescence emitted by each cell was recorded. Each dot represents a single cell. This plot of green fluorescence (vertical axis) versus red fluorescence (horizontal axis) for thousands of spleen cells shows that about half of them — the T cells — express both CD3 and Thy1 proteins on their surfaces (upper-right quadrant). The remaining cells, which exhibit low fluorescence (lower-left quadrant), express only background levels of these proteins and are other types of white blood cells. Note the logarithmic scale on both axes.

[Data from Chengcheng Zhang, Whitehead Institute.]

Flow cytometry can measure many different parameters in cells. For example, it can measure a cell's DNA content (from the amount of fluorescence emitted from a DNA-binding dye) and determine the general shape and size of a cell (from the amount of scattered light). Measurements of the DNA content of individual cells are used to follow replication of DNA as cells progress through the cell cycle (see Chapter 19). Flow cytometry can also be used to identify specific cell types in a population by using cell-type specific antibodies, each with a different fluorescent molecule attached. An example is distinguishing different cell types in blood samples. It can also be used to study signaling pathways at the single-cell level. Stimulation of many signaling pathways results in the phosphorylation of specific proteins (discussed in Chapters 15 and 16), and these can often be detected in cell populations by western

blot analysis using phospho-specific antibodies that recognize individual sites of phosphorylation on specific proteins (see Chapter 3). However, this yields a population average, so flow cytometry has been adapted to quantify the phosphorylation level of specific proteins in individual cells. Use is made of phospho-specific antibodies to which different fluorescent reporters have been covalently linked. For example one antibody might be linked to a fluorochrome that emits green fluorescence, and another antibody linked to one that emits red fluorescence. Cells are treated so that they are made permeable to antibodies, but their phosphorylated proteins are retained. The permeabilized cells are then incubated with phospho-specific antibodies and analyzed by flow cytometry to detect the degree of phosphorylation of the proteins, as reported by the amount of green or red signal. In this way, the level of protein phosphorylation can be assessed in response to activation of different signaling pathways.

An alternative method for separating specific types of cells uses small magnetic beads coupled to antibodies to a specific cell-surface molecule. For example, to isolate T cells, the beads are coated with a monoclonal antibody specific for a surface protein such as CD3 or Thy1. Only cells with these proteins will stick to the beads, which can be recovered from the preparation by attraction to a small magnet on the side of a test tube.

Growth of Cells in Two-Dimensional and Three-Dimensional Culture Mimics the In Vivo Environment

While much has been learned using cells grown on plastic or glass surfaces, these surfaces are far removed from cells' normal tissue environment. As detailed in Chapter 20, many cell types function only when closely linked to other cells. Key examples are the sheet-like layers of epithelial tissue, called **epithelia** (singular, **epithelium**), that cover the external and internal surfaces of organs. Typically, epithelial cells have distinct surfaces, called the *apical* (top), *basal* (base or bottom), and *lateral* (side) surfaces (see Figure 20-11). The basal surface usually contacts an underlying extracellular matrix called the *basal lamina*, whose composition and function are discussed in Section 20.3. Epithelial cells often function to transport specific classes of molecules across the epithelial sheet; for example, the epithelial lining of the intestine transports nutrients into the cell through the apical surface and out toward the bloodstream across the basolateral surface. When grown on plastic or glass, epithelial cells cannot easily perform this function. Therefore, special containers have been designed with a porous surface that acts as a basal lamina to which epithelial cells attach and form a uniform two-dimensional sheet (Figure 4-3). A commonly used cultured cell line derived from dog kidney epithelium, called the *Madin-Darby canine kidney* (*MDCK*) cell line, is often used to study the formation and function of epithelial sheets.

FIGURE 4-3 Madin-Darby canine kidney (MDCK) cells grown in specialized containers provide a useful experimental system for studying epithelial cells. MDCK cells form a polarized epithelium when grown on a porous membrane filter coated on one side with collagen and other components of the basal lamina. With the use of the special culture dish shown here, the medium on each side of the filter (apical and basal sides of the monolayer) can be experimentally manipulated and the movement of molecules across the layer monitored.

However, even a two-dimensional sheet often does not allow cells to fully mimic behavior in their normal environment. Methods have now been developed to grow cells in three dimensions by providing a support infiltrated with appropriate components of the extracellular matrix (discussed in Chapter 20). If MDCK cells are cultured under appropriate conditions, they will form a tubular sheet mimicking a tubular organ or the duct of a secretory gland. In these three-dimensional structures, the apical side of the epithelial sheet lines the lumen, whereas the basal side of each cell is in contact with the extracellular matrix (Figure 4-4).

EXPERIMENTAL FIGURE 4-4 MDCK cells can form cysts in culture. (a) MDCK cells grown on a supported extracellular matrix will form groups of cells that polarize to form a tubular single layer of cells with a lumen in the middle, called a *cyst*. (b) By examining the localization of proteins found in the apical (red) and basolateral membranes (green), we can see that these cells are fully polarized, with the apical side facing the lumen, which recapitulates their organization in the kidney tubules from which they are derived. The nuclear DNA is stained blue.

In a similar manner, primary hepatocytes (cells isolated from a liver) can now be isolated and cultured. Under proper conditions, they will form hepatocyte spheroids that can be maintained in culture and respond to drugs in much the same way that an intact liver does in living animals. These are just two examples of a growing field in which organ culture systems are being developed to more closely correspond to cells and tissues in living animals — and thereby expand the number of experiments that can be performed in a physiologically relevant manner.

Stem Cells Can Differentiate in Culture to Make Organoids

As we discuss in detail in Chapter 22, embryonic stem cells can be isolated from the inner cell mass of an early mammalian embryo. These cells are *pluripotent*, that is, they can give rise to all tissues of the embryo. Mature animals have *adult stem cells* in their tissues. These cells are not pluripotent, but are nevertheless crucial for cell regeneration or tissue repair. The division and differentiation of cells in an animal is orchestrated by many factors, including interactions with the extracellular matrix and other cells, response to soluble factors, and temporal changes in gene expression. With major advances in the study of the extracellular matrix (discussed in Chapter 20), signaling pathways elucidated by developmental studies (see Chapters 15 and 16), and the regulation of gene expression (discussed in Chapter 8), much has been learned about the molecular details of these differentiation pathways. It is now possible to recapitulate some of these developmental events in culture.

When adult stem cells from the intestine were placed in culture under appropriate conditions in a three-dimensional matrix, the cells formed intestinal organoids that had the normal crypt and villous structures of the small intestine. In a dramatic advance, researchers have used human pluripotent cells in culture to generate brain organoids whose organization and structure is

remarkably similar to the fetal brain (Figure 4-5). Organoids have now been developed for many organs, including the brain, intestines, stomach, kidney, heart, and tongue. So far, organoids advance to a stage of development characterized in the fetus, but do not proceed to the organization seen in an adult organ. These astonishing results reveal that cells possess the intrinsic program to divide, differentiate, and organize themselves into complex structures.

EXPERIMENTAL FIGURE 4-5 Brain organoid derived from pluripotent stem cells. In this section of the organoid, neural stem cells are labeled red and neurons are green. All cell nuclei are stained blue.

Besides being a remarkable achievement, what uses can be made of organoids? First, cells in an organoid can be followed much more easily than in a living animal. For example, in brain organoids, it

will be possible to examine early human brain development in much more detail. Second, stem cells used to generate organoids can be manipulated by introducing mutations and then observed to see how they affect the development of the organoid. Third, it is possible to test the effects of drugs on organoid development, which is much easier than in animals. Fourth, it has been found that tumor cells removed from a patient can be used to generate a morphologically characteristic tumor organoid in culture — which can be used to test the efficacy of potential drugs before they are administered to a patient. These are just a few of the remarkable uses for organoids; many more creative uses for both basic science and medicine are being developed.

Can we grow a whole organ that could be transplanted into a patient? As indicated above, organoids grown in culture so far do not develop into adult organs. However, recent advances in biomedical engineering are developing promising strategies to do this, initially in experimental animals. In an example of one approach, a 3-D printer is used to help make a replacement ear. First, an exact computer image of an ear is generated. This image is used to program a 3-D printer to assemble a pliable matrix — containing support material that is biodegradable, together with appropriate components of the extracellular matrix — in the precise shape of an ear. This matrix provides support for the growth of skin cells, either in culture or after transplantation under the skin, so that ultimately the synthetic organ can be surgically attached to a

living animal. Other approaches make use of 3-D printers to assemble the matrix and seed it with appropriate cells. An exciting and ambitious goal of this technology is to generate synthetic organs containing many different types of cells by printing each of several layers with the appropriate matrix and cells to generate complex three-dimensional organs that might one day be used to replace defective ones in patients. Many hurdles still need to be overcome, but the ability to generate stem cells from patients and then induce differentiation in culture is overcoming the major obstacle of immunological rejection and will probably be key to providing cells for the assembly of synthetic organs. ■

Hybridomas Produce Abundant Monoclonal Antibodies

In addition to serving as research models for studies of cell function, cultured cells can be converted into "factories" for producing specific proteins. For example, special cultured cells can be used to generate monoclonal antibodies, which are experimental tools widely used in many aspects of cell biological research. They are also used for diagnostic and therapeutic purposes in medicine, as we discuss in later chapters.

To understand the challenge of generating monoclonal antibodies, we must briefly review how mammals produce antibodies; more

detail is provided in Chapter 24. Recall that antibodies are proteins secreted by white blood cells that bind with high affinity to their antigen (see Figure 3-22). Each normal antibody-producing B lymphocyte in a mammal is capable of producing a single type of antibody that can bind to a particular determinant, or **epitope**, on an antigen molecule. An epitope is generally a small region on the antigen, consisting, for example, of just a few amino acids. If an animal is injected with an antigen, the B lymphocytes that make antibodies recognizing that antigen are stimulated to grow and secrete those antibodies. Each antigen-activated B lymphocyte forms a clone of cells in the spleen or lymph nodes, with each cell producing the identical antibody — that is, a **monoclonal antibody**. Because most natural antigens contain multiple epitopes, exposure of an animal to an antigen usually stimulates the formation of multiple B-lymphocyte clones, each producing a different antibody. The resulting mixture of antibodies from the many B-lymphocyte clones that recognize different epitopes on the antigen is said to be *polyclonal*. Such **polyclonal antibodies** circulate in the blood and can be isolated as a group.

Although polyclonal antibodies are very useful, monoclonal antibodies are more suitable for many types of experiments and medical applications in which we need a reagent that binds to just one site on a protein; for example, one that competes with a ligand on a cell-surface receptor. Unfortunately, the biochemical purification of any one type of monoclonal antibody from blood is

not feasible for two main reasons: the concentration of any given antibody is quite low, and all antibodies have the same basic molecular architecture (see Figure 3-22).

To produce and then purify monoclonal antibodies, one first needs to be able to grow the appropriate B-lymphocyte clone. However, primary cultures of normal B lymphocytes are of limited usefulness for the production of monoclonal antibodies because they have a limited life span. Thus the first step in producing a monoclonal antibody is to generate a library of immortal antibody-producing cells (Figure 4-6). Immortality is achieved by fusing normal B lymphocytes from an immunized animal with transformed, immortal lymphocytes called *myeloma cells* that themselves do not synthesize antibodies, and selecting for hybrid cells called a **hybridoma**. Like myeloma cells, hybridoma cells grow rapidly and are immortal. Each hybridoma produces the monoclonal antibody encoded by its B-lymphocyte parent. The library of hybridomas is then screened for clones that produce the desired antibody; any clone producing that antibody is then grown in large cultures, from which a substantial quantity of pure monoclonal antibody can be obtained.

FIGURE 4-6 Use of cell fusion and selection to obtain hybridomas producing a monoclonal antibody to a specific protein. Step 1: Immortal myeloma cells that cannot synthesize purines under special conditions because they lack thymidine kinase are fused with normal antibody-producing spleen cells from an animal that was immunized with antigen X. Step 2: When cultured in a

special selective medium, unfused and self-fused cells do not grow: the myeloma cells do not grow because the selective medium does not contain purines, and the spleen cells do not grow because they have a limited life span in culture. Thus only fused cells formed from a myeloma cell *and* a spleen cell survive in the selective medium, proliferating into clones called *hybridomas*. Each hybridoma produces a single antibody. Step **3**: Testing of individual clones identifies those that recognize antigen X. After a hybridoma that produces a desired antibody has been identified, the clone can be cultured to yield large amounts of that antibody.

Monoclonal antibodies are valuable research tools. They are commonly employed in affinity chromatography to isolate and purify proteins from complex mixtures (see Figure 3-43c). As we discuss later in this chapter, they are also employed in immunofluorescence microscopy to locate a particular protein within cells, and they are used in immunoblotting to identify specific proteins in cell fractions (see Figure 3-44).

Rabbit, mouse, and human immunoglobulins are built from two heavy chains and two light chains, with both the light and heavy chains contributing to the antigen binding site (see Figure 24-14). Remarkably, camelids (including camels and llamas) have these conventional immunoglobulins and immunoglobulins consisting of just two heavy chains. The antigen-combining site of these antibodies is relatively small, about 15 kDa compared with about 150 kDa for a whole mouse monoclonal antibody. Thus the camelid immunoglobulins are easily expressed in, and purified from, bacteria. Such so-called *nanobodies* with a single high-affinity

binding site for specific antigens are being developed for therapeutic, diagnostic, and research purposes.

Monoclonal antibodies have become important diagnostic and therapeutic tools in medicine as well. For example, monoclonal antibodies that bind to and inactivate toxins secreted by bacterial pathogens are used to treat certain infectious diseases.

The first monoclonal antibodies used for therapeutic purposes were made in mice. However, when used in humans these were recognized as foreign proteins and removed by the immune system. Subsequently, antibodies were engineered to contain mostly human sequences fused to the mouse antigen-binding regions. An early example of such a therapeutic antibody was the development of Herceptin for treatment of an aggressive form of breast cancer. It was known that these cancers overexpress HER2, a plasma membrane protein of the EGF receptor tyrosine kinase family (see Chapter 16). Monoclonal antibodies to the extracellular domain of HER2 were generated and screened for those that reduced HER2-overexpressing tumors in mice. Refining and humanizing this mouse monoclonal antibody resulted in the development of Herceptin, which has now been used to treat about a half million patients with HER2-positive breast cancer.

Therapeutic antibodies are available today with about 85–90 percent human sequences, although generating these is a technologically

complicated process. A much better solution would be to generate monoclonal antibodies directly from human B cells. Recently, such an approach has been made possible.

To make human monoclonal antibodies, many millions of naive B cells are isolated from removed tonsils. Since the isolated cells cannot be propagated indefinitely, the population is immortalized by infecting them with Epstein-Barr virus. The immortal naive B cells are induced to undergo class-switching and somatic mutations (discussed in Chapter 24) to generate an extensive library of B cells in which each clone secretes a specific monoclonal antibody. The library of B cells can then be screened with antigen for those that secrete the desired monoclonal antibody. In this way, it will be possible to isolate human-based therapeutic monoclonal antibodies.

A Wide Variety of Cell Biological Processes Can Be Studied with Cultured Cells

As we discussed in the introduction to this chapter, studying animal cells in culture is much easier than studying cells in intact animals, partly because they can easily be subjected to a variety of manipulations. Cultured cells are particularly useful for the elucidation of fundamental processes. One way to understand a

biological process is to interfere with a specific constituent in the cell and assess the outcome — this approach is like trying to understand how a car works by removing components and seeing what goes wrong. In some cases, human diseases associated with genetic defects in specific cell components can be analyzed using cells cultured from the patients. For example, analysis of cultured cells from patients with a genetic defect resulting in hypercholesterolemia — who have elevated blood cholesterol leading to heart disease and stroke — was critical in elucidating the basic steps of receptor-mediated endocytosis (see Chapter 14). In addition to relying on naturally occurring genetic lesions, we can manipulate cultured cells to interfere with expression of specific components. As we will see in Chapter 6, it is possible to decrease the expression of a specific protein in cultured cells by selectively knocking down the corresponding mRNA and then assess what effect this change has on particular processes in the cell. Chapter 6 also describes the more recently developed gene editing techniques that can be used to inactivate specific genes in the genomes of cultured cells and thereby assess how the complete loss of specific RNAs and proteins affects cell functions.

Drugs Are Commonly Used in Cell Biological Research

Another powerful way to analyze biological processes is to treat cells with drugs that bind to specific cell components and inactivate or activate them. In this section, we discuss how new drugs affecting specific cell processes can be developed.

Naturally occurring drugs have been used for centuries, but how they worked was often unknown. For example, extracts of meadow saffron were used to treat gout, a painful disease resulting from inflammation of joints. Today we know that this plant contains colchicine, a drug that depolymerizes microtubules (see Chapter 18) and interferes with the ability of white blood cells to move to sites of inflammation. Alexander Fleming discovered that certain fungi secrete compounds that kill bacteria (antibiotics), and his discovery resulted in the development of penicillin. Only later was it discovered that penicillin inhibits cell division by blocking the assembly of the cell walls of certain bacteria.

Discoveries like these have resulted in a wide range of drugs that can inhibit specific and essential processes of cells. In most cases, researchers have eventually been able to identify the molecular targets of these drugs. For example, there are many antibiotic drugs that affect aspects of prokaryotic protein synthesis.

How does one discover a new drug? One widely used approach is to search *chemical libraries*, consisting of tens to hundreds of thousands of different compounds, for chemicals that inhibit a specific process. The screening of chemical libraries in conjunction with

high-throughput microscopic techniques has now become one of the major routes for new leads in drug discovery. Here we give just one case to illustrate how this type of approach works.

In our example (Figure 4-7a), researchers wanted to identify compounds that inhibit mitosis, the process by which duplicated chromosomes are accurately segregated by a microtubule-based machine called the *mitotic spindle* (discussed in Chapter 18). It was known that if spindle assembly is compromised, cells are arrested in mitosis. Therefore, the screen first used an automated robotic method to look for compounds that arrest cells in mitosis. The basis for the inhibition of mitosis by the candidate compounds was then explored to see if they affected assembly of the microtubules. Since inhibition of microtubule assembly was not of interest, the effect of the remaining candidate compounds on the structure of the spindle was determined by immunofluorescence microscopy using antibodies to tubulin, the major protein of microtubules. Over 16,000 compounds were screened, and a compound was identified that resulted in cells with abnormal spindles — instead of having two asters, they had a single aster, resulting in what is called a *mono-astral array* (Figure 4-7b). This drug, now called *monastrol*, was found to interfere with the assembly of the spindle by inhibiting a microtubule-based motor protein called *kinesin-5*. (See Chapter 18 for more details about the mitotic spindle.) While monastrol did not have the appropriate properties for a clinically useful drug, other

kinesin-5 inhibitors have been developed that are now in clinical trials.

FIGURE 4-7 Screening for drugs that affect specific biological processes. (a) In this example, a chemical library of 16,320 different chemicals was subjected to a series of screens for inhibitors of mitosis. Since such an inhibitor is expected to arrest cells at the mitotic stage of the cell cycle, the first screen (step 1) was to see if any of the chemicals enhanced the level of a marker specific for mitotic cells; this screen yielded 139 candidates. Microtubules make up the structure of the mitotic spindle, and the researchers were not interested in new drugs that target microtubules, so in the second screen (step 2) they

tested the 139 compounds for their ability to affect microtubule assembly; this test eliminated 53 candidates. Immunofluorescence microscopy with antibodies to tubulin (the major subunit of microtubules), together with a stain for DNA, was then used in the third screen (step **3**) to identify compounds that disrupt the structure of the spindle. (b) Localization of tubulin (green) and DNA (blue) for an untreated mitotic spindle (*top*) and one treated with one of the five compounds remaining after screen, now called *monastrol*. Monastrol inhibits a microtubule-based motor protein called *kinesin-5*, discussed in Chapter 18, that is necessary to separate the poles of the mitotic spindle. When kinesin-5 is inhibited, the two poles remain associated to give a monopolar spindle.

KEY CONCEPTS OF SECTION 4.1

Growing and Studying Cells in Culture

- Animal cells have to be grown in culture under conditions that mimic their natural environment, which generally requires them to be supplied with necessary amino acids and growth factors.
- Most animal cells need to adhere to a solid surface to grow.
- Primary cells — those isolated directly from tissue — have a finite life span.
- Transformed cells, such as cells derived from tumors, can grow indefinitely in culture.
- Cells that can be grown indefinitely are called a *cell line*.
- Many cells lines are aneuploid, having a different number of chromosomes than the parent cell from which they were derived.
- Cells expressing a fluorescent protein can be sorted on a machine called a *fluorescence-activated cell sorter* (*FACS*) (see Figure 4-2).
- Different cell types express different marker proteins on their cell surfaces, which can be labeled with fluorescent markers, allowing them to be sorted on a FACS machine.
- Epithelial cells are often grown in special containers to mimic their functional polarity. Cells can also be grown on three-dimensional matrices to more accurately reflect their normal environment.

- Monoclonal antibodies, which bind one epitope on an antigen, can be secreted by cultured cells called *hybridomas*. These hybrid cells are made by fusing antibody-producing B lymphocytes with immortal myeloma cells and then identifying those clones that produce the desired antibody. Monoclonal antibodies are important for basic research and as therapeutic agents (see Figure 4.6).
- Cells in culture can be much more easily manipulated than cells in an intact animal.
- Basic biological processes can be studied by interfering with specific cell components, either through genetic mechanisms or by the application of specific drugs.
- Large chemical libraries can be screened for compounds that target specific processes to study those processes and to identify new drugs.

4.2 Light Microscopy: Exploring Cell Structure and Visualizing Proteins Within Cells

The cellular basis of life was first appreciated using primitive light microscopes. Since then, progress in cell biology has paralleled, and has often been driven by, technological advances in light microscopy (Figure 4-8). Here we discuss each of these major developments and how they advanced the study of cellular processes. First we describe basic uses of a light microscope to observe unstained cells and structures, or material treated with chemical stains. Next we describe how fluorescence microscopy is used to localize specific proteins in fixed cells. By using molecular genetic techniques to fuse a protein of interest with a naturally fluorescent protein and express the resulting chimeric protein in cells, it is possible to follow the movement of specific proteins in live cells — an ability that has revealed the dynamic organization of live cells. In parallel with these advances in specimen preparation, optical advances were being made that enhance and sharpen the images provided by fluorescence microscopy, revealing cellular structure with unprecedented resolution. Many specialized technologies have emerged from these advances, and we describe some of the more important ones.

FIGURE 4-8 Development of the light microscope. (a) Early microscopes, like the ones used by Robert Hooke in the 1660s, used lenses or a mirror to illuminate the specimen. (b) Optics in general, and light microscopes in particular, developed enormously during the nineteenth century. By the middle of the twentieth century, highly sophisticated microscopes limited only by the resolution of light were common. (c) In the second half of the twentieth century, fluorescence microscopy and digital imaging, together with confocal techniques, were developed to yield the versatile microscopes of today.

Many of the microscopy techniques we discuss allow one to examine live cells. These include *live cell imaging* as well as examining responses of live cells to a specific stimulus, such as a growth factor, or their interactions with other cells. These techniques have provided scientists with the ability to probe the functioning of individual components in live cells.

The Resolution of the Conventional Light Microscope Is About 0.2 μm

All microscopes produce a magnified image of a small object, but the nature of the image depends on the type of microscope

employed and on the way the specimen is prepared. The compound microscope, used in conventional *bright-field light microscopy*, contains several lenses that magnify the image of a specimen under study (Figure 4-9a, b). The total magnification is a product of the magnification of the individual lenses: if the *objective lens*, the lens closest to the specimen, magnifies hundredfold (a 100 × lens, the maximum usually employed), and the *projection lens* that focuses the image on a camera magnifies tenfold, the final magnification will be 1000-fold. Alternatively, if the light is directed to an ocular or *eyepiece* lens that magnifies tenfold, the final magnification recorded by the human eye will also be 1000-fold.

FIGURE 4-9 Optical microscopes are commonly configured for bright-field, phase-contrast, or fluorescence microscopy. (a) In a typical light microscope, the specimen is

usually mounted on a transparent glass slide and positioned on the movable specimen stage. (b) In bright-field light microscopy, light from a tungsten lamp is focused on the specimen by a condenser lens below the stage; the light travels the pathway shown in yellow. (c) In phase-contrast microscopy, incident light passes through an annular diaphragm, which focuses a circular annulus (ring) of light on the specimen. Light that passes unobstructed through the specimen is focused by the objective lens onto the thicker gray ring of the phase plate, which absorbs some of the direct light and alters its phase by one-quarter of a wavelength. If a specimen refracts (bends) or diffracts the light, the phase of some light waves is altered (green lines), and the light waves pass through the clear region of the phase plate. The refracted and unrefracted light is recombined at the image plane to form the image. (d) In fluorescence microscopy, a beam of light from a mercury lamp (gray lines) is directed to the excitation filter, which allows only the correct wavelength of light to pass through (green lines). The light is then reflected off a dichroic mirror and through the objective lens, which focuses it on the specimen. The fluorescent light emitted by the specimen (red lines) passes up through the objective lens, then through the dichroic mirror, and is focused and recorded on the detector at the image plane.

The most important property of any microscope, however, is not its magnification, but its resolving power, or **resolution**: the ability to distinguish between two very closely positioned objects. Merely enlarging the image of a specimen accomplishes nothing if the image is blurred. The resolution of a microscope lens is numerically equivalent to D, the minimum distance between two distinguishable objects. The smaller the value of D, the better the resolution. The value of D is given by the equation

$$D = \frac{0.61\lambda}{N \sin \alpha} \tag{4-1}$$

where α is the angular aperture, or half-angle, of the cone of light entering the objective lens from the specimen (Figure 4-9a), N is the refractive index of the medium between the specimen and the objective lens (i.e., the relative velocity of light in the medium compared with the velocity in air), and λ is the wavelength of the incident light. Resolution is improved by using shorter wavelengths of light (decreasing the value of λ) or by gathering more light (increasing either N or α). Lenses for high-resolution microscopy are designed to work with oil between the lens and the specimen under a thin glass coverslip, since oil has a higher refractive index (1.56, compared with 1.0 for air and 1.3 for water), and matching the refractive index more closely to that of glass (about 1.52) maximizes the recovered light. To maximize the angle α, and hence $\sin \alpha$, the lenses are also designed to focus very close to the thin coverslip covering the specimen. The term $N \sin \alpha$ is known as the *numerical aperture* (*NA*) and is usually marked on the objective lens. A good high-magnification lens has an NA of about 1.4, and the very best lenses — which cost as much as a medium-sized car — have a value approaching 1.5. Notice that the magnification is not part of this equation.

Owing to limitations in the values of α, λ, and N based on the physical properties of light, the *limit of resolution* of a microscope using light of wavelength 400 nm is about 0.2 μm (200 nm). No matter how many times the image is magnified, a conventional light microscope can never resolve objects that are closer than about

0.2 μm apart or reveal details smaller than about 0.2 μm in size. However, some newer and sophisticated technologies devised to overcome this resolution barrier can resolve objects that are just a few 10s of nanometers apart. We discuss such super-resolution microscopes in a later section.

Phase-Contrast and Differential-Interference-Contrast Microscopy Visualize Unstained Live Cells

Cells are about 70 percent water, 15 percent protein, and 6 percent RNA, and contain smaller amounts of lipids, DNA, and small molecules. Since none of these major classes of molecules are colored, and since they hardly impede the transmission of light, special methods must be used to see cells in a microscope. For example, the simplest microscopes view cells under *bright-field* optics (Figure 4-9b), and little detail can be seen (Figure 4-10, *left*). Two common methods for imaging live cells and unstained tissues to generate contrast take advantage of differences in the refractive index and thickness of cellular materials. These methods, called *phase-contrast microscopy* and *differential-interference-contrast (DIC) microscopy* (or *Nomarski interference microscopy*), produce images that differ in appearance and reveal different features of cell architecture. Figure 4-10 compares images of live, cultured cells obtained with these two methods and with standard bright-field

microscopy. Since optical microscopes are expensive, they are often set up to perform many different types of microscopy on the same microscope stand (see Figure 4-9a–d).

FIGURE 4-10 Live cells can be visualized by microscopy techniques that generate contrast by interference. These micrographs show live, cultured macrophage cells viewed by bright-field microscopy (*left*), phase-contrast microscopy (*middle*), and differential-interference-contrast (DIC) microscopy (*right*). In a phase-contrast image, cells are surrounded by alternating dark and light bands; in-focus and out-of-focus details are simultaneously imaged in a phase-contrast microscope. In a DIC image, cells appear in pseudorelief. Because only a narrow in-focus region is imaged, a DIC image is an optical slice through the object.

Phase-contrast microscopy generates an image in which the degree of darkness or brightness of a region of a specimen depends on the *refractive index* of that region. Light moves more slowly in a medium with a higher refractive index. Thus a beam of light is refracted (bent) once as it passes from the medium into a transparent object and again when it departs. In a phase-contrast microscope, a cone of light generated by an annular diaphragm in the condenser lens illuminates the specimen (see Figure 4-9c). The light passes through the specimen into the objective lens, and the unobstructed direct light passes through a region of the phase plate that both transmits

only a small percentage of the light and changes its phase slightly. The part of a light wave that passes through a specimen will be refracted and will be out of phase (out of synchrony) with the part of the wave that does not pass through the specimen. How much their phases differ depends on the difference in refractive index along the two paths and on the thickness of the specimen. The refracted and unrefracted light is recombined at the image plane to form the image. If the two parts of the light wave are recombined, the resultant light will be brighter if they are in phase and less bright if they are out of phase (Figure 4-10, *middle*). Phase-contrast microscopy is suitable for observing single cells or thin cell layers, but not thick tissues. It is particularly useful for examining the location and movement of larger organelles in live cells.

DIC microscopy, which is based on splitting the light into two perpendicular components before passing them through the specimen and then recombining them to observe their interference pattern, is the method of choice for visualizing extremely small details and thick objects. Contrast is generated by differences in the refractive index of the object and of its surrounding medium. In DIC images, objects appear to cast a shadow to one side. The shadow primarily represents a difference in the refractive index of a specimen rather than its topography. DIC microscopy easily defines the outlines of large organelles, such as the nucleus and vacuole. In addition to having a three-dimensional appearance, a DIC image is a thin *optical section*, or slice, through the object (Figure 4-10, *right*).

Thus details of the nucleus in thick specimens (e.g., an intact *Caenorhabditis elegans* roundworm; see Figure 22-26d) can be observed in a series of such optical sections, and the three-dimensional structure of the object can be reconstructed by combining the individual DIC images. Both phase-contrast and DIC microscopy can be used in *live cell microscopy*, in which the same cell is imaged at regular intervals over time to generate a movie that allows the observer to study cell movement.

Imaging Subcellular Details Often Requires That Specimens Be Fixed, Sectioned, and Stained

As we have seen, live cells and tissues generally do not absorb light, so they are nearly invisible in a light microscope. Although cells can be visualized by the special techniques we have just discussed, these methods do not reveal the fine details of structure.

Specimens for light microscopy are commonly fixed with a solution containing chemicals that cross-link most proteins and nucleic acids. Formaldehyde, a common fixative, cross-links amino groups on adjacent molecules; these covalent bonds stabilize protein-protein and protein–nucleic acid interactions and render the molecules insoluble and stable for subsequent procedures. After fixation, a tissue sample for examination by light microscopy is

usually embedded in paraffin and cut into sections about 5-μm thick (Figure 4-11a). Cultured cells growing on glass coverslips are thin enough to be fixed in situ and visualized by light microscopy without the need for sectioning.

FIGURE 4-11 Tissues for light microscopy are commonly fixed, embedded in a solid medium, and cut into thin sections. (a) A fixed tissue is dehydrated by soaking in a series of alcohol-water solutions, ending with an organic solvent compatible with the embedding medium. To embed the tissue for sectioning, the tissue is placed in liquid paraffin. After the block containing the specimen has hardened, it is mounted on the arm of a microtome, and slices are cut with a knife. Typical sections cut for light microscopy are $5\text{-}\mu\text{m}$ thick. The sections are collected on microscope slides and stained with an appropriate agent. (b) Sections of normal (*top*) and cancerous (adenocarcinoma, *bottom*) human colon stained with H&E stain. Notice the disorganization of the cells in the cancer tissue.

Finally, a specimen for light microscopy is stained, allowing the main structural features of the cell or tissue to be clearly seen. Many chemical stains bind to molecules that have specific features. For example, histological samples are often stained with *hematoxylin* and *eosin* ("H&E stain"). Hematoxylin binds to basic amino acids (lysine and arginine) on many different kinds of proteins, whereas eosin binds to acidic molecules (e.g., DNA and side chains of the amino acids aspartate and glutamate). Because of their different binding properties, these dyes stain various cell types sufficiently differently that they are distinguishable visually (Figure 4-11b). If an enzyme catalyzes a reaction that produces a colored or otherwise

visible precipitate from a colorless precursor, that enzyme can be detected in cell sections by their colored reaction products. Such staining techniques, although once quite common, have been largely replaced by other techniques for visualizing particular proteins, as we discuss next.

Fluorescence Microscopy Can Localize and Quantify Specific Molecules in Live Cells

Perhaps the most versatile and powerful technique for localizing molecules within a cell by light microscopy is **fluorescent staining** of cells and observation by *fluorescence microscopy*. A chemical is said to be *fluorescent* if it absorbs light at one wavelength (the excitation wavelength) and emits light (fluoresces) at a specific longer wavelength. Fluorescence microscopes allow the excitation light to pass through the objective lens into the sample and then permit the user to selectively observe the emitted fluorescent light coming back through the objective lens from the sample. This is achieved by using a special type of filter, called a *dichroic mirror*, that reflects the excitation light into the sample and allows the longer wavelength light emitted by the fluorescent sample to pass through to the observer (see Figure 4-9d). Here we discuss several ways in which fluorescence microscopy can be used to examine specific molecules in cells.

Intracellular Ion Concentrations Can Be Determined with Ion-Sensitive Fluorescent Dyes

The concentration of Ca^{2+} or H^{+} within live cells can be measured with the aid of fluorescent dyes, or *fluorochromes*, whose fluorescence depends on the concentration of these ions. As discussed in later chapters, intracellular Ca^{2+} and H^{+} concentrations have pronounced effects on many cellular processes. For instance, many hormones and other stimuli cause a rise in cytosolic Ca^{2+}, from the resting level at less than 10^{-7} M up to 10^{-5} or 10^{-4} M, that induces various cellular responses, such as the contraction of muscle.

Introduction of the fluorochrome *Fura-2*, which binds a single Ca^{2+}, can be used to follow transient increases of Ca^{2+} in living cells. This binding, which is proportional to the cytosolic Ca^{2+} concentration over a certain range, increases the fluorescence of Fura-2 at one particular wavelength. At a second wavelength, the fluorescence of Fura-2 is the same whether or not Ca^{2+} is bound and thus provides a measure of the total amount of Fura-2 in a region of the cell. By examining cells continuously in the fluorescence microscope and measuring rapid changes in the ratio of Fura-2 fluorescence at the two wavelengths, one can quantify rapid changes in the fraction of Fura-2 that has bound a Ca^{2+} ion, and thus in the concentration of

cytosolic Ca^{2+}. Although Fura-2 has been used extensively to study Ca^{2+} levels, as we discuss later in this chapter, heterologous expression of a protein Ca^{2+} sensor, which becomes fluorescent upon binding Ca^{2+}, has largely replaced the use of Ca^{2+}-sensitive dyes.

Fluorescent dyes that are sensitive to H^+ concentrations can be used to monitor the cytosolic pH of live cells. Other useful probes consist of a fluorochrome linked to a weak base that is only partially protonated at neutral pH and thus can freely permeate cellular membranes. In acidic organelles, however, these probes become protonated. Because the protonated probes cannot recross the organelle membrane, they accumulate in the lumen at concentrations much greater than in the cytosol. Thus this type of fluorescent dye can be used to specifically stain particular organelles in live cells, such as lysosomes and mitochondria shown in Figure 4-12.

EXPERIMENTAL FIGURE 4-12 Location of lysosomes and mitochondria in a cultured living bovine pulmonary artery endothelial cell. The cell was stained with a green-fluorescing dye that is specifically bound to mitochondria and a red-fluorescing dye that is specifically incorporated into lysosomes. The image was

sharpened using a deconvolution computer program discussed later in the chapter. N, nucleus.

Immunofluorescence Microscopy Can Detect Specific Proteins in Fixed Cells

The common chemical dyes mentioned above stain nucleic acids or broad classes of proteins, but it is much more informative to detect the presence and location of specific proteins. *Immunofluorescence microscopy*, the most widely used method of detecting specific proteins, uses an antibody to which a fluorescent dye has been covalently attached. To use this method, one must first generate antibodies to the specific protein of interest. As discussed briefly in Section 4.1 and in detail in Chapter 24, when an experimental animal is injected with an antigen, the vertebrate immune system responds by generating polyclonal antibodies that recognize different epitopes on the antigen. The antibodies that specifically recognize the antigen can be purified from all the other antibodies and proteins in blood serum by affinity chromatography over a resin on which the antigen is immobilized (see Figure 3-43c). Alternatively, as we described earlier in this chapter, it is possible to generate a clonal cell line that secretes antibodies to a specific epitope on the antigen; these are called *monoclonal antibodies*.

To use either type of antibody to localize a cytosolic protein, the cells or tissue must first be fixed to ensure that all components remain in place, and the cell must be permeabilized to allow entry of the antibody, which is commonly done by incubating the cells with a non-ionic detergent or by extracting the lipids with an organic solvent. To localize just a surface protein, the cell is fixed, but there is no need to permeabilize it. In one version of immunofluorescence microscopy, the antibody is covalently linked to a fluorochrome. Classically used fluorochromes include rhodamine and Texas red, which emit red light; Cy3, which emits orange light; and fluorescein, which emits green light; but newer and more photostable fluorochromes, with emission wavelengths from blue to far-red, have now been developed. When a fluorochrome-antibody complex is added to a permeabilized cell or tissue section, the complex will bind to the corresponding antigen, then light up when illuminated at the excitation wavelength. Staining a specimen with different dyes that fluoresce at different wavelengths allows multiple proteins as well as DNA to be localized within the same cell.

The most commonly used variation of this technique is called *indirect immunofluorescence microscopy* because the antibody specific to the protein of interest is detected indirectly. In this technique, an unlabeled monoclonal or polyclonal antibody is applied to the specimen, followed by a second, fluorochrome-tagged antibody that binds to the constant (Fc) segment of the first antibody. For example,

a secondary antibody can be generated by immunizing a goat with the Fc segment that is common to all rabbit immunoglobulin G antibodies. When coupled to a fluorochrome, this second antibody preparation (called *goat–anti-rabbit*) will detect any rabbit antibody used to stain a tissue or cell (Figure 4-13). Because several goat–anti-rabbit antibody molecules can bind to a single rabbit antibody molecule in a specimen, the fluorescence is generally much brighter than if a single fluorochrome-tagged antibody were used. This approach is often extended to do *double-label fluorescence microscopy*, in which two proteins can be visualized simultaneously. For example, two proteins can be visualized by indirect immunofluorescence microscopy using primary antibodies made in different animals (e.g., rabbit and chicken) and secondary antibodies (e.g., goat–anti-rabbit and sheep–anti-chicken) labeled with different fluorochromes. In another variation, one protein can be visualized by indirect immunofluorescence microscopy and the second protein by a dye that specifically binds to it. Once the individual images are taken on the fluorescence microscope, they can be merged electronically (Figure 4-14, and see chapter-opening figure).

FIGURE 4-13 A specific protein can be localized in fixed tissue sections by indirect immunofluorescence microscopy. (a) To localize a protein by immunofluorescence microscopy, a tissue section, or sample of cells, must be chemically fixed and made permeable to antibodies (step 1). The sample is then incubated with a primary antibody that binds specifically to the antigen of interest, and unbound antibody is then removed by washing (step 2). The sample is next incubated with a fluorochrome-labeled secondary antibody that specifically binds to the primary antibody, and again, excess secondary antibody is removed by washing (step 3). The sample is then mounted in specialized mounting medium and examined in a fluorescence microscope (step 4). (b) In this example, a section of the rat intestinal wall was stained with Evans blue, which generates a nonspecific red fluorescence, and GLUT2, a glucose transport protein, was localized by indirect immunofluorescence microscopy. GLUT2 (yellow) is seen to be present in the basal and lateral sides of the intestinal cells, but is absent from the brush border, composed of closely packed microvilli on the apical surface facing the intestinal lumen. Capillaries run through the lamina propria, a loose connective tissue beneath the epithelial layer.

[Part (b) from B. Thorens et al., 1990, *Am. J. Physiol.* **259**:C279;]

EXPERIMENTAL FIGURE 4-14 Double-label fluorescence microscopy can visualize the relative distributions of two proteins. In double-label fluorescence microscopy, each protein must be labeled with a different fluorochrome. (a) A cultured cell was fixed and permeabilized and then

incubated with Rhodamine-labeled phalloidin, a reagent that specifically binds to filamentous actin. It was also incubated with rabbit antibodies to tubulin, the major component of microtubules, followed by a fluorescein-labeled secondary goat–anti-rabbit antibody. (b) The upper panels show the fluorescein-stained tubulin (*left*) and Rhodamine-stained actin (*right*), and the lower panel shows the electronically merged images.

In another widely used version of this technology, molecular genetic techniques are used to make a cDNA encoding a recombinant protein to which is fused a short sequence of amino acids called an *epitope tag*. When expressed in cells, this cDNA will generate the protein linked to the specific tag. Two commonly used epitope tags are FLAG, which encodes the amino acid sequence DYKDDDDK (single-letter amino acid code), and Myc, which encodes the sequence EQKLISEEDL. Commercial fluorochrome-coupled monoclonal antibodies to the FLAG or Myc epitopes can then be used to detect the recombinant protein in the cell. In an extension of this technology to allow the simultaneous visualization of two proteins, one protein can be tagged with FLAG and a different protein with Myc. Each tagged protein is then visualized with a different color, for example, with a labeled antibody emitting green light for the Myc epitope and a labeled antibody emitting red light to the FLAG epitope. One has to use caution in studying expressed tagged proteins to ensure that the tag does not interfere with the protein's function or location.

Tagging with Fluorescent Proteins Allows the Visualization of Specific Proteins in Live Cells

The jellyfish *Aequorea victoria* expresses a naturally fluorescent protein, called *green fluorescent protein* (*GFP*, ~27 kDa). GFP contains a serine, tyrosine, and glycine sequence whose side chains spontaneously cyclize to form a green-fluorescing fluorochrome when illuminated with blue light. Using recombinant DNA technology, it is possible to make a DNA construct in which the coding sequence of GFP is fused to the coding sequence of a protein of interest. When this construct is introduced into and expressed in cells, a GFP-tagged protein is made in which the protein of interest is covalently linked to GFP as part of the same polypeptide. Although GFP is a medium-sized protein, the function of the protein of interest is often not changed by fusing it to GFP. This technique allows one to visualize GFP — and hence the location of the protein of interest. Not only can we see the location of the GFP-tagged protein immediately but we can also view its distribution in a live cell over time and thereby assess its dynamics or track its localization following various treatments, such as the application of specific drugs. The simple idea of tagging specific proteins with GFP revolutionized cell biology and led to the subsequent development of many different fluorescent proteins (Figure 4-15). Use of this colorful variety of fluorescent proteins allows one to visualize two or more proteins simultaneously if they are each tagged with a

different-colored fluorescent protein. We describe additional techniques that exploit fluorescent proteins in the following sections.

FIGURE 4-15 Many different colors of fluorescent proteins are available. (a) Tubes show the emission colors and names of many different fluorescent proteins. (b) An agar dish is illuminated to show growing bacteria expressing several different-colored fluorescent proteins.

Deconvolution and Confocal Microscopy Enhance Visualization of Three-Dimensional Fluorescent Objects

Conventional fluorescence microscopy has two major limitations. First, the fluorescent light emitted by a sample comes not only from the plane of focus but also from molecules above and below it; thus the observer sees a blurred image caused by the superposition of fluorescent images from molecules at many depths in the cell. The blurring effect makes it difficult to determine the actual spatial arrangements. Second, to visualize thick specimens, consecutive (serial) images at various depths throughout the sample must be collected and then aligned to reconstruct structures in the original thick tissue. Two general approaches have been developed to obtain high-resolution three-dimensional information. Both of these methods require that the image be collected electronically so that it can then be computationally manipulated as necessary.

The first approach, called *deconvolution microscopy*, uses computational methods to remove fluorescence contributed by out-of-focus parts of the sample. Consider a three-dimensional sample in which images from three different focal planes are recorded. Since the whole sample is illuminated, the image from plane 2 will contain out-of-focus fluorescence from planes 1 and 3. If we knew

exactly how out-of-focus fluorescence from planes 1 and 3 contributed to the light collected in plane 2, we could computationally remove it. To obtain this information for a particular microscope, we can make a series of images of focal planes from a test slide containing tiny fluorescent beads. Each bead represents a pinpoint of light that becomes a blurred object outside its focal plane; from these images we can determine a *point spread function* that enables us to calculate the distribution of fluorescent point sources that contributed to the blur when out of focus. Once we have calibrated the microscope in this manner, the experimental series of images can be computationally deconvolved. Microscopes with automated stages to collect the images, and associated software programs to deconvolve the images, are available commercially. Images restored by deconvolution display impressive detail without any blurring, as illustrated in Figure 4-16.

EXPERIMENTAL FIGURE 4-16 Deconvolution fluorescence microscopy yields high-resolution optical sections. A cultured cell in mitosis was stained with fluorochrome-labeled reagents specific for DNA (blue), microtubules (green), and the microfilament-membrane linking protein ezrin (red). A series of fluorescent images were obtained at consecutive focal planes (optical sections) through the cell. A single plane is shown in which the left half is a raw image and the right half has been subjected to deconvolution processing. Notice how much clearer the chromosomes (blue) and microtubules (green) are after processing.

The second approach to obtaining better three-dimensional information is called *confocal microscopy* because it uses optical

methods to obtain images from a specific focal plane and exclude light from other planes. Confocal microscopes collect a series of images focused through the vertical depth of the sample, from which an accurate three-dimensional representation can be computationally generated. Two types of confocal microscopes are in common use today, a *point-scanning* confocal microscope (also known as a *laser-scanning confocal microscope*, or *LSCM*) and a *spinning disk* confocal microscope. The idea behind each microscope is to both illuminate and collect emitted fluorescent light from just one small area of a focal plane at a time in such a way that out-of-focus light is excluded. This can be achieved by collecting the emitted light through a pinhole before it reaches the detector — light from the illuminated focal plane passes through, whereas light from other focal planes is largely excluded. The illuminated area is then moved across the whole focal plane to build up the image electronically. The two types of microscopes differ in how they cover the image. The point-scanning microscope uses a point laser light source at the excitation wavelength to rapidly scan the focal plane in a raster pattern, collects the emitted fluorescence in a photomultiplier tube, and thereby builds up an image (Figure 4-17a). It can then take a series of images at different depths in the sample to generate a three-dimensional reconstruction. A point-scanning confocal microscope can provide exceptionally high-resolution images in both two and three dimensions (Figure 4-18), although it has two minor limitations. First, it can take significant time to scan each focal plane, so if a very dynamic live cell process is being

imaged, the microscope may not be able to collect images fast enough to follow the dynamics. Second, it illuminates each spot with intense laser light, which can bleach the fluorochrome being imaged and damage live cells by phototoxicity, thereby limiting the number of images that can be collected.

FIGURE 4-17 Light paths for two types of confocal microscopy. Both types of microscopy are assembled around a conventional fluorescence microscope (yellow shading). (a) Light path in a point-scanning confocal microscope. A single-wavelength point of light from an appropriate laser is reflected off a dichroic mirror and bounces off two scanning mirrors and from there passes through the objective lens to illuminate a spot in the specimen. The scanning mirrors rock back and forth in such a way that the light scans the specimen in a raster fashion (see green lines in the specimen). The fluorescence emitted by the specimen passes back through the objective lens and is bounced off the scanning mirrors and through the dichroic mirror. This allows the light to pass toward the pinhole. This pinhole excludes light from out-of-focus focal planes, so the light reaching the photomultiplier tube comes almost exclusively from the illuminated spot in the focal plane. A computer then takes these signals and reconstructs the image. (b) Light path in a spinning disk confocal microscope. Here, instead of using two scanning mirrors, the beam from the laser is spread to illuminate pinholes on the coupled spinning disks, the first consisting of microlenses to focus the light

on pinholes in the second disk. The excitation light passes through the objective lens to provide point illumination of a number of spots in the specimen. The fluorescence emitted passes back through the objective lens and through the holes in the spinning disk, and is then bounced off a dichroic mirror into a sensitive digital camera. The pinholes in the disk are arranged so that as it spins, it rapidly illuminates all parts of the specimen several times. As the disk spins as fast as 5000 rpm, very dynamic events in live cells can be recorded.

FIGURE 4-18 Confocal microscopy produces an in-focus optical section through thick cells. A mitotic fertilized egg from a sea urchin (*Psammechinus*) was lysed with a detergent, exposed to a tubulin antibody, and then exposed to a fluorescein-tagged antibody that binds to the anti-tubulin antibody. (a) When viewed by conventional fluorescence microscopy, the mitotic spindle is blurred. This blurring occurs because background fluorescence is detected from tubulin above and below the focal plane as depicted in the sketch. (b) The confocal microscopic image is sharp, particularly in the center of the mitotic spindle. In this case, fluorescence is detected only from molecules in the focal plane, generating a very thin optical section.

[Micrographs © 1987 White et al., *J. Cell Biol.* **105**:41–48. https://doi.org/10.1083/jcb.105.1.41]

The spinning disk microscope circumvents these two limitations (Figure 4-17b). The excitation light from a laser is spread out and illuminates a small part of a disk spinning at high speed; for example, at 5000 rpm. The disk in fact consists of two linked disks: one with 20,000 lenses that precisely focuses the laser light on 20,000 pinholes of the second disk. The pinholes are arranged in such a way that they completely scan the focal plane of the sample several times with each turn of the disk. The emitted fluorescent light returns through the pinholes of the second disk and is reflected by a dichroic mirror and focused onto a highly sensitive digital camera. In this way, the sample is scanned in less than a millisecond, so the real-time location of a fluorescent reporter can be captured even if it is highly dynamic (Figure 4-19). A limitation of the spinning disk microscope is that the pinhole size is generally fixed and has to be matched to the magnification of the objective lens, so it is generally configured for use with a 63× or 100× objective and is less useful for the lower magnification imaging that might be required in tissue sections. However, recently, spinning disk head units have become available in which the pinhole size can be changed to better accommodate objectives with other magnifications. Thus the point-scanning and spinning disk confocal microscopes have overlapping and complementary strengths.

EXPERIMENTAL FIGURE 4-19 The dynamics of microtubules can be imaged on the spinning disk confocal microscope. Six frames from a movie of GFP-tubulin in two rod-shaped cells of fission yeast are shown. Arrowheads indicate examples of shrinking and growing microtubules.

Two-Photon Excitation Microscopy Allows Imaging Deep into Tissue Samples

We have just seen how point-scanning confocal microscopy can help reduce fluorescence from out-of-focus planes. To achieve this, it focuses a cone of laser light on a spot that scans across the focal plane. Regions above and below the focal plane are also illuminated by this cone of light, generating an out-of-focus signal that must be removed by collecting the light through a pinhole. This intense cone of light can also lead to photobleaching (rendering the fluorescent protein inactive) or damage to the sample by phototoxicity. If the sample is very thin, these are not significant problems, but as the sample gets thicker, they become more relevant. To circumvent these problems, use was made of the finding that a fluorochrome can be excited either by a single photon — for example, at 488 nm — or by two photons of half the energy at 960 nm, either of which will generate the same emission wavelength (Figure 4-20a). Thus if a 960-nm cone of laser light is focused on a spot in one plane so that only at the focal point is there sufficient density of photons to excite the

fluorochrome (Figure 4-20b), no out-of-focus signal will be obtained and less photobleaching or phototoxicity will occur. Because only fluorochromes in the focal plane are excited, two-photon microscopy can be used to explore much thicker samples, and there is no need for a pinhole to exclude out-of-focus light. Moreover, 960-nm light can penetrate more deeply into biological material than can 488-nm light. However, very high laser intensity is required for two-photon excitation microscopy, as the two photons must arrive within about a femtosecond of each other, which is achieved using rapid laser pulses. If individual cells in an animal express different color variants of fluorescent proteins, two-photon microscopy can be used to observe events in living animals (called *intravital imaging*) within about 1 mm of the surface (Figure 4-20c).

FIGURE 4-20 Two-photon excitation microscopy restricts illumination to the focal plane to allow deep penetration for intravital imaging. (a) Different excitation methods are used for conventional point-scanning confocal microscopy and for two-photon excitation microscopy. In the conventional system, absorption of a single photon of the appropriate wavelength (here at 488 nm, blue arrow) causes an electron to jump to the excited state. After undergoing vibrational relaxation (black dashed arrow), the electron falls back to the ground state with emission of one photon at a longer (lower energy) wavelength, in this case 507 nm (green arrow). In two-photon excitation, when two photons of the appropriate wavelength (shown here at 960 nm, red arrows) arrive almost instantaneously, they can both be absorbed and induce the electron to jump to the excited state. The electron undergoes some vibrational relaxation (black dashed arrow) and falls back to the ground state with the emission of a photon (507 nm). (b) A cuvette of fluorescent material is illuminated with 488-nm light (*left*), as in conventional confocal microscopy, or with intense 960-nm light, as in two-photon microscopy. Notice that the conventional system produces a bright cone of excitation outside the focal plane, whereas two-photon excitation illuminates just one spot in the focal plane. (c) An example of intravital imaging in which labeled neurons in a lobster were imaged.

TIRF Microscopy Provides Exceptional Imaging in One Focal Plane

The confocal microscopes we have just described provide amazing and informative images, but they are not perfect. Scientists continue to develop systems that are optimized for special circumstances. Some experimental situations call for fluorescence imaging in a thin focal plane adjacent to a surface, where it would be optimal to minimize out-of-focus background. For example, confocal imaging is not ideal for exploring the details of proteins at adhesion sites between a cell and a coverslip, or for following the kinetics of assembly of microtubules attached to a coverslip. Both of these situations can be imaged at high sensitivity using *total internal reflection fluorescence* (*TIRF*) microscopy, in which only the portion of the specimen immediately adjacent to the coverslip is illuminated. In the most common configuration of TIRF microscopy, the excitation light comes through the objective lens. However, the angle at which the light arrives at the coverslip is adjusted to be slightly larger than the critical angle θ_c so that the light is reflected off the coverslip and returns up through the objective (Figure 4-21a). This generates a narrow band of light, called an *evanescent wave*, that

illuminates only about 50–100 nm of the sample adjacent to the coverslip (2–4 times the thickness of a microtubule), with no illumination of the rest of the sample. Thus if you have a complex mixture of fluorescent structures in a specimen, the TIRF microscope will show you only those that are within 50–100 nm of the coverslip. TIRF has been exceptionally useful in identifying structures on the bottoms of cells grown on a coverslip (Figure 4-21b) and for measuring the kinetics of assembly and disassembly of structures such as microtubules and actin filaments (see Chapters 17 and 18).

EXPERIMENTAL FIGURE 4-21 Fluorescent samples in a restricted focal plane can be imaged by total internal reflection fluorescence (TIRF) microscopy. (a) Illumination setup for TIRF microscopy. The angle at which light becomes reflected from a glass-water interface is called the *critical angle* θ_c. Below this angle, the beam of light will pass into the specimen; above θ_c, it will be reflected. In TIRF microscopy, the angle of the incident beam θ_c, resulting in most of the light being reflected, but also generating a very thin region of illumination called the evanescent wave (depicted in light green). (b) Immunofluorescence microscopy with tubulin antibody was used to visualize microtubules viewed by conventional fluorescence microscopy (*top*) and by TIRF (*middle*), and a merged image was created from the two views (*bottom*). The two images were collected and false-colored red and green so that the merge could highlight those microtubules that are close to the coverslip (green).

FRAP Reveals the Dynamics of Cellular Components

Live cell fluorescence imaging reveals the locations and bulk dynamics of populations of fluorescent molecules, but it doesn't tell you how dynamic individual molecules are. For example, if we see that a GFP-labeled protein forms a patch at the surface of a cell, does this represent a stable collection of fluorescent protein molecules or a dynamic equilibrium, with fluorescent proteins coming in and out of the patch? We can investigate this question by observing the dynamics of the molecules in the patch (Figure 4-22). If we use a high-intensity light to permanently bleach the fluorochrome (e.g., GFP) in the patch, initially there will be no fluorescence coming from it, and it will look dark in the fluorescence microscope. However, if the components in the patch are in dynamic equilibrium with unbleached molecules elsewhere in the cell, the bleached molecules will be replaced by unbleached ones, and the fluorescence will begin to come back. The rate of fluorescence recovery is a measure of the dynamics of the molecules. This technique, known as *fluorescence recovery after photobleaching* (*FRAP*), has revealed how very dynamic many components of cells are. For example, it has been used to determine

the diffusion coefficient of cytoskeletal and membrane proteins (see Figure 10-10). In another approach to measuring the dynamics of tagged proteins, variants of fluorescent proteins have been developed that can be switched, using a laser of an appropriate wavelength, from emitting green light to emitting red light. In this way, the dynamics of the switched population of red-emitting molecules can be imaged in live cells.

EXPERIMENTAL FIGURE 4-22 Fluorescence recovery after photobleaching (FRAP) reveals the dynamics of molecules. In a live cell, following the distribution of a GFP-labeled protein provides a view of the overall distribution of the protein, but it doesn't tell us how dynamic

populations of individual molecules might be. (a) In FRAP, the GFP fluorochrome is bleached by a short burst of strong laser light focused on the region of interest (ROI). The light rapidly bleaches the molecules irreversibly, so they are not detected again. Restoration of fluorescence in the region tells us that unbleached molecules have moved into the ROI. (b) FRAP was used to determine the exchange rate of EBP50 and ezrin, two components of microvilli (seen as white lines), on the apical surface of epithelial cells. In cells expressing either GFP-EBP50 or ezrin-GFP, the GFP in a small region indicated by the green box was bleached, and recovery by exchange with unbleached protein was followed. The fluorescence of GFP-EBP50 returns very fast, indicating it has a fast exchange rate, whereas the fluorescence of ezrin-GFP returns slowly, indicating a slower exchange rate. (c) By quantifying the recovery, the dynamic properties of EBP50 and ezrin can be established.

FRET Measures Distance Between Fluorochromes

Fluorescence microscopy can also be used to determine if two proteins interact in vivo by taking advantage of a phenomenon called **Förster resonance energy transfer (FRET)**. This technique uses a pair of fluorescent proteins in which the emission wavelength of the first is close to the excitation wavelength of the second (Figure 4-23a). For example, when cyan fluorescent protein (CFP) is excited with 433-nm light, it fluoresces and emits light at 475 nm. If yellow fluorescent protein (YFP) is close by, however, instead of emitting 475-nm light, CFP transfers energy to YFP by FRET, and YFP emits light at 530 nm. The efficiency of FRET is proportional to R^{-6}, where R is the distance between the fluorochromes; it is therefore very

sensitive to small changes in distance and in practice is not detectable at distances greater than 10 nm. Thus by illuminating an appropriately prepared sample with 433-nm light and observing at 530 nm, one can tell if proteins separately tagged with CFP and YFP are in very close proximity. For example, FRET sensors have been developed to determine where signaling between a small GTP-binding regulatory protein and its effector occurs in the cell (Figure 4-23b).

FIGURE 4-23 Protein-protein interactions can be visualized by FRET. The idea behind FRET is to use two different fluorescent proteins so that when one is excited, energy will be transferred to the second one by FRET, provided that they are sufficiently close. (a) In this

example, cyan fluorescent protein (CFP) is fused to protein X, yellow fluorescent protein (YFP) is fused to protein Y, and both proteins are expressed in a live cell. If the cell is now illuminated with 433-nm light, the CFP will emit a fluorescent signal at 475 nm. If YFP is not close by (*left*), energy transfer will not occur, and no 530-nm light will be emitted. However, if protein X interacts with protein Y (*right*), it will bring CFP close to YFP, energy will be transferred to YFP by FRET, and YFP will emit light at 530 nm. (b) In this mouse fibroblast, FRET has been used to reveal that the interaction between an active regulatory protein (Rac) and its binding partner is localized to the front of the migrating cell.

[Part (b) ©2003 R. B. Sekar and A. Periasamy, 2003, *J. Cell Biol.* **160**:629–633. https://doi.org/10.1083/jcb.200210140]

A clever application of FRET, called a *FRET biosensor*, can be used to sense local biochemical environments in live cells. The idea is to express a single polypeptide containing both CFP and YFP separated by a region that undergoes a conformational change when it senses a biochemical signal. In the absence of the signal, CFP and YFP are too far apart to undergo significant FRET. However, when the signal is detected, the conformational change brings CFP and YFP close enough together to generate FRET. A version of this technique can be used to measure the local activity of a specific protein kinase. In this case, between the CFP and YFP lies a region of polypeptide containing the substrate for the protein kinase — the *sensor domain* — and a domain that binds specifically to the phosphorylated substrate — the *ligand domain* (Figure 4-24a). When the sensor domain is phosphorylated by the kinase, the ligand domain binds to it and brings the CFP and YFP sufficiently close to undergo FRET. Since protein phosphorylation is a dynamic process, dephosphorylation of the sensor domain by the appropriate

phosphatase will deactivate the FRET biosensor. Thus the FRET signal will reflect the regions of the cell where there is excess kinase over phosphatase activity. As an example, scientists have developed a FRET biosensor for protein kinase A activity, which is activated by elevation of the signaling molecule cAMP (see Section 15.1). In cells expressing the protein kinase A biosensor, pharmacological elevation of cAMP induces rapid FRET (Figure 4-24b). Creative researchers are developing FRET biosensors to illuminate many different types of local environments; for example, FRET biosensors exist to measure the concentration and location of Ca^{2+} (see Figure 4-27) and the activation state of GTPase switch proteins (see Figure 3-35).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 4-24 FRET biosensors can detect local biochemical environments. (a) A FRET biosensor is a fusion protein containing two fluorescent proteins linked by a region sensitive to the environment under study. In this example, a protein construct consists of CFP linked to YFP by a region that contains a particular sequence that can be phosphorylated by a specific kinase (the sensor domain) and a region (the ligand domain) that binds the sensor domain when it is phosphorylated. In the absence of kinase activity, the two fluorescent proteins are too far apart to undergo FRET, whereas when locally phosphorylated by the active kinase, the sensor domain becomes phosphorylated, the ligand domain binds to it, and CFP and YFP are brought sufficiently close to undergo FRET. The sensor can also be deactivated when it encounters the appropriate phosphatase that removes the added phosphate. Thus the biosensor reports on the ratio of kinase to phosphatase activity in the local environment. (b) An example of the use of a FRET biosensor for protein kinase A, which is activated by elevation of cAMP. In this example, forskolin, a drug that induces the generation of cAMP, was added to cells at $t = 0$ and the

images collected at various times thereafter. Imaging shows both the rate of activation and localization of the active kinase.

Optogenetics Allows Light to Regulate Events in a Spatial and Temporal Manner

The idea that light can be used to control biochemical reactions in living cells arose from the study of phototaxis (attraction to light) of the green alga *Chlamydomonas reinhardtii*. Scientists discovered that a pulse of bright light induced the opening of a cation channel in a protein now known as *channelrhodopsin*. When channelrhodopsin is expressed in neurons, the opening of the channel by light allows the very rapid influx of Na^+ that depolarizes the membrane. As we will see in Chapter 23, expression of channelrhodopsins in specific neurons combined with localized pulses of light can be used to dissect neural circuits.

In a subsequent advance, methods were developed to use light to control biochemical reactions locally. This technology grew out of the identification of proteins that control plant phototropism (orientation toward, or away, from light). One of these, using the light sensitive LOV domain, has been extensively used. In an

example to demonstrate the utility of this approach, light was used to induce an engineered protein located in the nucleus to move into the cytoplasm. As described in Chapter 13, proteins that are targeted to the nucleus contain a short nuclear localization sequence (NLS), and those that are exported from the nucleus have a short nuclear export sequence (NES) that can interact with a protein called an *exportin* to transport it out into the cytoplasm. A multidomain construct was made containing the following parts: Fluorescent protein-NLS-LOV-NES (Figure 4-25a). The construct was made so that in the dark the NLS sequence was accessible, whereas the NES was masked. When expressed in cells in the dark, the protein is located in the nucleus as expected because NES cannot interact with exportin (Figure 4-25a, *top*). However, when illuminated, the LOV domain changes conformation, releasing the NES, which can now bind exportin (Figure 4-25a, *bottom*). This change results in export of the protein from the nucleus. When the illumination is turned off, the LOV domain reverses its conformation, masking the NES, and the protein returns to the nucleus (Figure 4-26b). If instead of the fluorescent protein a nuclear regulator was made part of the construct, this would allow light-mediated regulation of its activity. This type of approach has been used in many different settings, for example, to recruit proteins to the plasma membrane or to activate signaling pathways.

EXPERIMENTAL FIGURE 4-25 Use of the LOV domain and light to alter the localization of a protein. (a) In this example, a construct was made in which a fluorescent protein was fused to a nuclear localization sequence (NLS), the LOV domain, and a nuclear export sequence (NES). In the dark the NES sequence is not accessible to interact with exportin (Exp), but when illuminated a conformational change in the LOV domain releases the NES that can now interact with exportin. (b) When this construct is expressed in cells, the construct localizes to the nucleus because the NLS sequence is accessible, whereas the NES sequence is not. However, upon illumination of a single cell with blue light (box), the LOV domain undergoes a conformational change, releasing the NES so that it is accessible to exportin and the protein is then transported out of the nucleus. This is reversible, as the protein returns to the nucleus when the illumination is turned off. The images in (b) show an inverted fluorescence image of the cells expressing the construct.

EXPERIMENTAL FIGURE 4-26 Super-resolution microscopy can generate light-microscope images with up to nanometer resolution. The theoretical resolution of the light microscope can be circumvented by super-resolution microscopy. (a) In structured illumination microscopy (SIM), the sample is illuminated by a pattern of light and dark stripes and several images are taken as the illumination is rotated. This technique generates interference patterns that can be mathematically reconstructed to generate a higher-resolution image. The images on the right show similar fields of the nucleus (lamin, green; DNA, magenta) imaged by conventional point-scanning confocal microscopy and by SIM, which improves resolution about twofold. (b) In stimulated emission depletion (STED) microscopy, the sample is scanned as in point-scanning microscopy, but with a very small

point of light, generated by an emission laser and confined by a donut-shaped stimulated emission depletion zone. The sample at the right shows part of a cell stained for actin fibers after imaging by point-scanning microscopy and by STED. (c) In photoactivated localization microscopy (PALM), use is made of a variant of GFP that can be photoactivated by a wavelength different from its excitation wavelength. When a small number of GFP molecules are activated, and then excited, each will emit thousands of photons that can be collected. This generates a Gaussian curve centered on the location of the emitting GFP; the center provides the location of the GFP to nanometer accuracy. This process is reiterated hundreds of times to excite other GFP molecules, and a high-resolution image emerges. At right, a confocal image of microtubules is compared with a corresponding super-resolution image in which the three-dimensional arrangement of the microtubules is color coded.

Point Source Fluorescent Objects Can Be Located at Nanometer Resolution

Although a conventional microscope cannot resolve two objects closer together than 200 nanometers, it can localize a stationary single object to within a few nanometers. If we have a point-source of fluorescence — say, a single fluorescently tagged protein — and use a sensitive camera to rapidly collect and image multiple photons, this will generate a Gaussian curve of fluorescence

intensity around the precise position of the tagged protein. A computer can then calculate the average position to reveal the center of the object to within a few nanometers. In this way, computer algorithms can be used to track the position of single objects, or even moving objects as long as the exposure time for each image is sufficiently short so that the object does not move appreciably. As we discuss in a later chapter, this technique has been used to measure nanometer-sized steps as molecules and vesicles move along cytoskeletal filaments (see Figures 17-28 and 17-29).

Super-Resolution Microscopy Can Localize Proteins to Nanometer Accuracy

As we discussed earlier, the theoretical resolution limit of the fluorescence microscope is about 0.2 μm (200 nm). Two new general approaches, collectively known as *super-resolution microscopy*, have been developed to get around this limitation. In the first type of approach, the illuminating light is patterned in such a way that higher resolution images are obtained. In *structured illumination microscopy* (*SIM*), the specimen is illuminated with a pattern of light and dark stripes, and several images are taken as the illuminating pattern is rotated. Computational analysis of the images gives a resolution of about 100 nm, twice that of a conventional confocal

microscope, as can be seen in a micrograph of invaginations in part of the nuclear envelope (Figure 4-26a). SIM is especially good for live cell imaging, as three-dimensional images can be collected every 4 seconds. In *stimulated emission depletion* (*STED*) *microscopy*, the sample is scanned just as in point-scanning microscopy, but with an important difference: the focused excitation laser point is surrounded by a donut-shaped depletion beam, which effectively makes the area excited much smaller. Since the computer records the precise position of the spot excited and can record the emission from it, it can build up an impressive image, optimally yielding a resolution of 30 nm, greatly enhancing the detail one can see, for example, in an image of actin fibers (Figure 4-26b).

The second general approach uses point-source detection and localization as described in the previous section. To understand how this works, consider two fluorescent spots separated by 75 nm. When you try to image them together, they each generate a Gaussian distribution of fluorescence that overlaps so much that they look like one spot. However, if you could image each spot individually and find the center of each Gaussian curve, you could beat the resolution limit and detect the two spots 75 nm apart. One way to do this, called *photoactivated localization microscopy* (*PALM*), also known as *stochastic optical reconstruction microscopy* (*STORM*), relies on the ability of a variant of GFP to be photoactivated; that is, it can become fluorescent only after being activated by a specific wavelength of light, different from its excitation wavelength.

Consider what happens when we activate just one such GFP molecule. When we then excite the sample, the one activated GFP emits many hundreds of photons, giving rise to a Gaussian distribution (Figure 4-26c). Although analysis of each photon does not tell us precisely where the GFP is, the center of the distribution can tell us where the GFP is located with nanometer accuracy. If we now activate another GFP, we can localize it individually with the same precision. In PALM/STORM, a small percentage of GFPs are activated and each localized with high precision, and then another set is activated and localized, and as additional cycles of activation and localization are recorded, a high-resolution image emerges. In practice, super-resolution images have a resolution of about 30 nm in the focal plane, and 50 nm perpendicular to it. For example, the three-dimensional distribution of microtubules can be seen with much greater clarity than with conventional fluorescence microscopy (see Figure 4-26c). These types of images can take significant time to generate, so their use on samples of live cells is so far restricted. Nevertheless, because of the tremendous benefits of super-resolution microscopy, enormous efforts are being made to improve its sensitivity, speed, and spatial resolution, and we can expect rapid progress in the development of these approaches. Indeed, a new variation of STED combined with PALM/STORM, called *MINFLUX*, has been reported to result in a resolution close to 1 nm, although it has so far only been used in very specialized situations.

Light-Sheet Microscopy Can Rapidly Image Cells in Living Tissue

Most of the confocal imaging approaches we have discussed above illuminate and detect fluorochromes through the same objective lens; this ensures that the excitation of the sample and the imaging of the emitted fluorescence occur in the same focal plane. As a result of this approach, there are limitations on the depth of sample that can be imaged. A new technology has been developed to get around this limitation. In *light-sheet microscopy*, the sample is illuminated from the side and then viewed in an orthogonal direction (Figure 4-27a). A focused laser beam sweeps back and forth across the sample, illuminating a single plane. A detection objective, at right angles to the illuminated plane, then images the sample. To generate a three-dimensional image, all the planes in the sample have to be imaged. This is achieved by coordinately stepping the illuminating sheet and detection objective through the sample to generate a stack of images, which can then be assembled computationally into a three-dimensional rendering.

FIGURE 4-27 Light-sheet microscopy can image rapid events in living tissue. (a) In light-sheet microscopy, a tissue sample is illuminated from the side by a focused laser beam that scans the sample (arrows) to generate a sheet of light. The sample is observed in the orthogonal direction through the detection objective. To get a three-dimensional image, the illuminating and detection objectives are moved coordinately, taking images throughout the depth of the sample. (b) The Ca^{2+} biosensor known as GCaMP. This biosensor is made using recombinant DNA techniques to generate a polypeptide to which the N- and C-termini of GFP are fused and the middle interrupted. On one side of the interruption is the sensor domain, consisting of the Ca^{2+}-binding protein calmodulin. On the other side is the ligand domain, consisting of a target sequence to which calmodulin will bind in the presence of Ca^{2+}. In the absence of Ca^{2+}, the GFP is not functional due to the interruption. In the presence of Ca^{2+}, calmodulin binds four Ca^{2+} ions and undergoes a conformational change that allows it to bind the ligand domain. This conformational change brings the two parts of GFP into close proximity so that the fluorescent protein is functional. (c) Local increases in the level of Ca^{2+}, false-colored red, in cells of the brain of a living zebrafish.

In one example of the use of this technology, scientists have imaged concentrations of Ca^{2+} in the cells of a living zebrafish brain. The neurons in the brain of the zebrafish were made to express a Ca^{2+} biosensor, called *GCaMP*, which is based on GFP that does not fluoresce in the absence of Ca^{2+} but is designed to fluoresce in its presence (Figure 4-27b). This biosensor consists of GFP in which the N- and C-terminal domains are connected, but the middle of the protein is interrupted. A Ca^{2+} sensor domain is attached to one end of the GFP and a ligand domain to the other end. Because the structure of GFP is interrupted, the protein no longer fluoresces when excited by the appropriate illuminating light. The sensor domain is derived from the small Ca^{2+}-binding protein calmodulin (see Figure 3-34), which changes its conformation when it binds four Ca^{2+} ions. The ligand domain binds calmodulin only after calmodulin is activated by binding Ca^{2+}. When active calmodulin binds the ligand domain, it changes the conformation of the interrupted GFP in such a way that it can now be excited and fluoresce. In this way, a fluorescent signal is reported whenever Ca^{2+} levels rise sufficiently to activate calmodulin. As we discuss in Chapter 23, when neurons communicate, part of this communication involves an elevation in Ca^{2+} levels. This neuronal

communication can be nicely imaged by light-sheet microscopy in vivo in the brain of a living zebrafish expressing the GCaMP biosensor (Figure 4-27c).

KEY CONCEPTS OF SECTION 4.2

Light Microscopy: Exploring Cell Structure and Visualizing Proteins Within Cells

- The resolution of the light microscope, about $0.2\ \mu\mathrm{m}$, is limited by the wavelength of light.
- Differences in refractive index can be used to observe parts of single cells by employing phase-contrast and differential-interference-contrast microscopy.
- Tissues generally have to be fixed, sectioned, and stained for cells and subcellular structures to be observed.
- Fluorescence microscopy makes use of compounds that absorb light at one wavelength and emit it at a longer wavelength.
- Ion-sensitive fluorescent dyes can measure intracellular concentrations of ions, such as Ca^{2+}.
- Immunofluorescence microscopy makes use of antibodies to localize specific components in fixed and permeabilized cells.
- Indirect immunofluorescence microscopy uses an unlabeled primary antibody that recognizes a specific protein, followed by a fluorescently labeled secondary antibody that recognizes the primary one and allows it to be visualized.
- Short sequences encoding epitope tags can be appended to protein-coding sequences to allow localization of the expressed protein using an antibody to the epitope tag.
- Green fluorescence protein (GFP) and its derivatives are naturally occurring fluorescent proteins.
- Expressing a fusion of GFP to a protein of interest allows its localization and dynamics to be explored in a live cell.
- Deconvolution and confocal microscopy provide greatly improved clarity in fluorescent images by removing out-of-focus fluorescent light.
- Total internal reflection fluorescence (TIRF) microscopy allows fluorescent samples adjacent to a coverslip to be seen with great clarity.
- Fluorescence recovery after photobleaching (FRAP) allows the dynamics of a population of molecules to be analyzed.

- Förster resonance energy transfer (FRET) is a technique in which light energy is transferred from one fluorescent protein to another when the proteins are very close, thereby revealing when two molecules are close in the cell.
- Optogenetics allows in vivo imaging to follow the effect of local and rapid biochemical changes induced by light.
- Super-resolution microscopy allows for detailed fluorescent images at nanometer resolution.
- Light-sheet microscopy can provide fluorescent images of thick samples by illuminating the sample with a sheet of light from the side.

4.3 Electron Microscopy: High-Resolution Imaging

Electron microscopic imaging of biological samples, such as single proteins, organelles, cells, and tissues, offers a much higher resolution of ultrastructure than can be obtained by light microscopy. The short wavelength of electrons means that the limit of resolution for a transmission electron microscope is theoretically 0.005 nm (much less than the diameter of a single atom) or 40,000 times better than that of a light microscope and 2 million times better than that of the unaided human eye. However, the effective resolution of the transmission electron microscope in the study of biological systems is considerably less than this ideal. Under optimal conditions, a resolution of 0.10 nm can be obtained with transmission electron microscopes, about 2000 times better than with conventional light microscopes.

The fundamental principles of electron microscopy are similar to those of light microscopy; the major difference is that in electron microscopes, electromagnetic lenses focus a high-velocity electron beam instead of the visible light used by optical lenses. In **transmission electron microscopy (TEM)**, electrons are emitted from a filament and accelerated in an electric field (Figure 4-28, *left*). A condenser lens focuses the electron beam onto the sample; objective and projector lenses focus the electrons that pass through the specimen and project them onto a viewing screen or other

detector. Because atoms in air absorb electrons, the entire tube between the electron source and the detector is maintained under an ultrahigh vacuum. Thus living material cannot be imaged by electron microscopy.

FIGURE 4-28 In electron microscopy, images are formed from electrons that pass through a specimen or are scattered from a metal-coated specimen. In a

transmission electron microscope (TEM, *left*), electrons are extracted from a heated filament, accelerated by an electric field, and focused on the specimen by a magnetic condenser lens. Electrons that pass through the specimen are focused by a series of magnetic objective and projector lenses to form a magnified image of the specimen on a detector, which may be a fluorescent viewing screen, a photographic film, or a charged-couple-device (CCD) camera. In a scanning electron microscope (SEM, *right*), electrons are focused by condenser and objective lenses on a metal-coated specimen. Scanning coils move the beam across the specimen, and electrons scattered from the metal are collected by a photomultiplier tube detector. In both types of microscopes, because electrons are easily scattered by air molecules, the entire column is maintained at a very high vacuum.

In this section, we describe various approaches to viewing biological material by electron microscopy. The most widely used instrument is the transmission electron microscope, but also in common use is the *scanning electron microscope* (*SEM*), which provides complementary information, as we discuss at the end of this section (Figure 4-28, *right*).

Single Molecules or Structures Can Be Imaged Using a Negative Stain or Metal Shadowing

It is common in biology to explore the detailed shapes of single macromolecules, such as proteins or nucleic acids, or of structures, such as viruses and the filaments that make up the cytoskeleton. It is

relatively easy to view these objects in the transmission electron microscope, provided they are stained with a heavy metal that scatters the incident electrons. A sample is prepared first by adsorbence to a 3-mm *electron microscope grid* (Figure 4-29a), which is coated with a thin film of plastic and carbon. The sample is then bathed in a solution of a heavy metal, such as uranyl acetate, and excess solution is removed (Figure 4-29b). As a result of this procedure, the uranyl acetate coats the grid, but is excluded from the regions where the sample has adhered. When we view the sample in the TEM, we see where the stain has been excluded, so the sample is said to be *negatively stained*. Because the stain can precisely reveal the topology of the sample, a high-resolution image can be obtained (Figure 4-29c).

Part (c) CDC/Maureen Metcalfe; Azaibi Tamin, Ph.D.

FIGURE 4-29 Transmission electron microscopy of negatively stained samples reveals fine features. (a) Samples for transmission electron microscopy (TEM) are usually mounted on a small copper or gold grid. The grid is usually covered

with a very thin film of plastic and carbon to which a sample can adhere. (b) The specimen is then incubated in a heavy metal, such as uranyl acetate, and excess stain is removed. (c) The sample excludes the stain, so when it is observed in the TEM, it is seen in negative outline. The example in (c) is a negative stain of a coronavirus, very similar to the one that caused the COVID-19 pandemic.

Samples can also be prepared by *metal shadowing* (Figure 4-30). In this technique, the sample is adsorbed to a small piece of mica, then coated with a thin film of platinum by evaporation of the metal, and dissolved with acid or bleach, leaving the platinum coating (known as a replica). When the replica is transferred to a grid and examined in the TEM, it provides information about the three-dimensional topology of the sample.

FIGURE 4-30 Metal shadowing makes surface details on very small objects visible by transmission electron microscopy. (a) The sample is spread on a mica surface and then dried in a vacuum evaporator (step 1). The sample grid is coated with a thin film of a heavy metal, such as platinum or gold, evaporated from an electrically heated metal filament (step 2). To stabilize the replica, the specimen is then coated with a carbon film evaporated from an overhead electrode (step 3). The biological material is then dissolved by acid and bleach (step 4), and the remaining metal replica is viewed in a TEM. (b) A platinum-shadowed replica of poliovirus particles.

Cells and Tissues Are Cut into Thin Sections for Viewing by Electron Microscopy

Single cells and pieces of tissue are too thick to be viewed directly in the standard transmission electron microscope. To overcome this problem, methods were developed to prepare and cut *thin sections* of cells and tissues. When these sections were examined in the electron microscope, the organization, beauty, and complexity of the cell interior was revealed and led to a revolution in cell biology — for the first time, new organelles and the first glimpses of the cytoskeleton were seen.

To prepare thin sections, it is necessary to chemically fix the sample, dehydrate it, impregnate it with a liquid plastic that hardens (similar to Plexiglas), and then cut sections of about 5 to 100 nm in thickness. For structures to be seen, the sample has to be stained with heavy metals such as uranium and lead salts, which can be done either before embedding in the plastic or after sections are cut. Examples of cells and tissues viewed by thin-section electron microscopy appear here (Figure 4-31) and throughout this book. It is important to realize that the images obtained represent just a thin slice through a cell, so to get a three-dimensional view, it is necessary to cut *serial sections* through the sample and reconstruct the sample from a series of sequential images (Figure 4-32).

FIGURE 4-32 Model of the Golgi complex based on three-dimensional reconstruction of electron microscopy images. Transport vesicles (white spheres) that have budded off the rough ER fuse with the *cis* membranes (light blue) of the Golgi complex. By mechanisms described in Chapter 14, proteins move from the *cis* region to the *medial* region and finally to the *trans* region of the Golgi complex. Eventually, vesicles that bud off the *trans*-Golgi membranes (orange and red) move either to the cell surface or to lysosomes. The Golgi complex, like the rough endoplasmic reticulum, is especially prominent in secretory cells.

Immunoelectron Microscopy Localizes Proteins at the Ultrastructural Level

Just as immunofluorescence microscopy is used for localizing proteins at the light-microscope level, methods have been developed to use antibodies to localize proteins in thin sections at the electron microscope level. However, the harsh procedures used to prepare traditional thin sections — chemical fixation and embedding in plastic — can denature or modify the antigens so that they are no longer recognized by specific antibodies. Gentler methods have been developed, such as light fixation, sectioning of material after freezing at the temperature of liquid nitrogen, and finally incubation with antibody at room temperature. To make the antibody visible in the electron microscope, it must be attached to

an electron-dense marker. One way to do this is to use electron-dense gold particles coated with protein A, a bacterial protein that binds the Fc segment of all antibody molecules (Figure 4-33). Because the gold particles diffract incident electrons, they appear as dark spots.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 4-33 Gold particles coated with protein A are used to detect an antibody-bound protein by transmission electron microscopy. (a) First, antibodies are allowed to interact with their specific antigen in a section of

fixed tissue. Then the section is treated with electron-dense gold particles coated with protein A from the bacterium *Staphylococcus aureus*. Binding of the bound protein A to the Fc domains of the antibody molecules makes the location of the target protein visible in the electron microscope. (b) HIV particle budding from an infected HeLa cell. A cryosection of the specimen was prepared and first incubated with an antibody to capsid protein, then with protein A–coated 5-nm gold particles to localize the internal capsid protein. The unoccupied sites in the protein A were inactivated, and the specimen was incubated with antibody to the membrane-bound Env protein, followed by protein A–coated 10-nm gold particles. The distinct localization of the 5-nm gold labeling the capsid protein and the 10-nm gold labeling the Env protein can be seen. Scale bar is 100 nm.

Cryoelectron Microscopy Allows Visualization of Specimens Without Fixation or Staining

Standard transmission electron microscopy cannot be used to study live cells, and the absence of water in samples causes macromolecules to become denatured and nonfunctional. However, hydrated, unfixed, and unstained biological specimens can be viewed directly in a transmission electron microscope if the samples are frozen. In **cryoelectron microscopy**, an aqueous suspension of a sample is applied to a grid in an extremely thin film, frozen in liquid nitrogen, and maintained in this state by means of a special mount. The frozen sample is then placed in the electron microscope. The very low temperature ($-196\ ^\circ\mathrm{C}$) keeps water from evaporating, even in a vacuum. Thus the sample can be observed in

detail in its native, hydrated state without fixing or heavy metal staining. By computer-based averaging of hundreds of images, a three-dimensional model can be generated almost to atomic resolution. For example, this method was used to generate models of ribosomes and the muscle calcium pump discussed in Chapter 11. Over the last few years, techniques have been developed to use cryoelectron microscopy to determine the atomic structures of large proteins and protein complexes. This technique, described in detail in Chapter 3, involves taking up to a million images of different orientations of the molecules embedded in ice and then using computational analysis to generate a detailed, three-dimensional structure. This approach has revolutionized structural biology because it does not require the formation of protein crystals, as is required for x-ray crystallography.

An extension of this technique, *cryoelectron tomography*, allows researchers to determine the three-dimensional architecture of organelles or even whole cells embedded in ice, that is, in a state close to life. A single picture is a two-dimensional representation of a structure that lacks depth information. However, looking at the same structure from different angles gives us a three-dimensional perspective. In cryoelectron tomography, the specimen holder is tilted in small increments around the axis perpendicular to the electron beam; thus images of the object viewed from different directions are obtained (Figure 4-34a, b). The images are then merged computationally into a three-dimensional reconstruction

termed a *tomogram* (Figure 4-34c, d). A disadvantage of cryoelectron tomography is that the samples must be relatively thin, about 200 nm; this is much thinner than the samples (200-μm thick) that can be studied by confocal light microscopy.

FIGURE 4-34 Structure of the nuclear pore complex (NPC) imaged by cryoelectron tomography. (a) In cryoelectron tomography, a semicircular series of two-dimensional projection images is recorded from the three-dimensional specimen that is located at the center; the specimen is tilted while the electron optics and detector remain stationary. The three-dimensional structure is then computed from the collected two-dimensional images. (b) Isolated nuclei from the cellular slime mold *Dictyostelium discoideum* were quick-frozen in liquid nitrogen and maintained in this state as the sample was observed in the electron microscope. The panel shows three sequential, tilted images. Different orientations of NPCs

(arrows) are shown in top view (*left* and *center*) and side view (*right*). Ribosomes connected to the outer nuclear membrane are visible, as is a patch of rough ER (arrowheads). (c) Computer-generated surface-rendered representation of a segment of the nuclear envelope membrane (yellow) studded with NPCs (blue). (d) By averaging the images of multiple nuclear pores, much more detail can be discerned. See S. Nickell et al., 2006, *Nat. Rev. Mol. Cell Biol.* **7**:225.

Scanning Electron Microscopy of Metal-Coated Specimens Reveals Surface Features

Scanning electron microscopy (SEM) allows investigators to view the surfaces of unsectioned metal-coated specimens. An intense electron beam inside the microscope scans rapidly over the sample. Molecules in the coating are excited and release secondary electrons that are focused onto a scintillation detector; the resulting signal is displayed on a cathode-ray tube much like a conventional television (see Figure 4-28, *right*). The resulting scanning electron micrograph has a three-dimensional appearance because the number of secondary electrons produced by any one point on the sample depends on the angle of the electron beam in relation to the surface (Figure 4-35). The resolving power of scanning electron microscopes, which is limited by the thickness of the metal coating,

is only about 10 nm, much less than that of transmission instruments.

FIGURE 4-35 Scanning electron microscopy (SEM) produces a three-dimensional image of the surface of an unsectioned specimen. Seen here is an SEM image of cells of the trachea. In the middle is a goblet cell, which secretes mucus. On either side of the goblet cell are epithelial cells with abundant cilia on their apical surfaces.

KEY CONCEPTS OF SECTION 4.3

Electron Microscopy: High-Resolution Imaging

- Electron microscopy provides very high-resolution images because of the short wavelength of the high-energy electrons used to image the sample.
- Simple specimens, such as proteins or viruses, can be negatively stained or shadowed with heavy metals for examination in a transmission electron microscope (TEM).

- Thicker sections generally must be fixed, dehydrated, embedded in plastic, sectioned, and then stained with electron-dense heavy metals before viewing by TEM.
- Specific proteins can be localized by TEM by employing specific antibodies associated with a heavy metal marker, such as small gold particles.
- Cryoelectron microscopy allows examination of hydrated, unfixed, and unstained biological specimens in the TEM by maintaining them at very low temperatures.
- Scanning electron microscopy (SEM) of metal-shadowed material reveals the surface features of specimens.

4.4 Isolation of Cell Organelles

The examination of cells by light and electron microscopy led to the appreciation that eukaryotic cells contain a common set of organelles, introduced in Chapter 1 (see Figure 1-13a). However, observing organelles and documenting their detailed structure by microscopy does not clearly reveal the roles they play and how they work. For this, it is necessary to isolate organelles in their native state and identify and dissect the function of each component. For this reason, methods to isolate and characterize organelles were developed in parallel with advances in microscopy. Lysosomes, for example, are organelles in which biological molecules are degraded, as described in Chapter 1. Lysosomes had been seen by microscopy, but their function was discovered only after a method was developed to isolate them. When a method is developed to purify a type of organelle, it is possible to begin to catalogue all of its components and probe the function of each one. In another example, electron microscopy revealed that some ribosomes are associated with the endoplasmic reticulum, suggesting that the ER is a site of protein synthesis. We now know that proteins to be secreted from the cell are made by these ribosomes and that the nascent secretory protein is translocated across the membrane into the lumen of the endoplasmic reticulum. As we describe in Chapter 13, understanding the mechanism by which this occurs depended on the isolation of the endoplasmic reticulum and the development of in vitro assays for the synthesis and translocation of secretory

proteins. Thus before one can begin to fully understand organelles, biochemical assays need to be established to probe the functions of each component, with the eventual goal of reconstituting functional organelles from purified components.

Most organelles are enclosed in a lipid bilayer and perform a specific function. Each type of organelle has a recognizable structure and contains a specific set of proteins to perform its function. Cell biologists use this fact to identify specific organelles. For example, as discussed in Chapter 12, most of the ATP in a cell is made by ATP synthase, which converts ADP to ATP in mitochondria, so ATP synthase is a good marker for mitochondria. As we will discuss below, the availability of specific markers for organelles has helped in the development of organelle purification.

In this section, we discuss methods that are used to open up cells for the purification of organelles. We end with recent advances in proteomics aimed at defining the complete protein inventories of organelles.

Disruption of Cells Releases Their Organelles and Other Contents

The initial step in purifying subcellular structures is to release the cell's contents by rupturing the plasma membrane and the cell wall, if present. To do this, the cells are suspended in a solution of

appropriate pH and salt content, usually isotonic sucrose (0.25 M) or a combination of salts similar in composition to those in the cell's interior. Many cells can then be broken by stirring the cell suspension in a high-speed blender or by exposing it to ultrahigh-frequency sound (*sonication*). Alternatively, plasma membranes can be sheared by special pressurized tissue homogenizers in which cells are forced through a very narrow space between a plunger and the wall of the vessel; the pressure of being forced between the vessel wall and the plunger ruptures the cell.

Recall that water flows into cells when they are placed in a hypotonic solution; that is, one with a lower concentration of ions and small molecules than is found inside the cell. This osmotic flow can be used to cause cells to swell, weakening the plasma membrane and facilitating its rupture. Generally the cell solution is best kept at 0 °C to preserve enzymes and other constituents after their release from the stabilizing forces of the cell.

Disrupting the cell produces a mix of suspended cellular components, the *homogenate*, from which the desired organelles can be retrieved. Because rat liver contains an abundance of a single cell type, this tissue has been used in many classic studies of cell organelles. However, the same isolation principles apply to virtually all cells and tissues, and modifications of these cell-fractionation techniques can be used to separate and purify any desired components.

Centrifugation Can Separate Many Types of Organelles

In Chapter 3, we considered the principles of centrifugation and the uses of centrifugation techniques for separating proteins and nucleic acids. Since different organelles have characteristic densities because of different membrane, protein, and nucleic acid composition, similar approaches can be used for separating them. Organelles differ in both size and density and thus undergo sedimentation at different rates.

Most cell-fractionation procedures begin with *differential centrifugation* of a filtered cell homogenate at increasingly higher speeds (Figure 4-36). After centrifugation at each speed for an appropriate time, the liquid that remains at the top of the vessel, called the *supernatant*, is poured off and centrifuged at higher speed. The pelleted fractions obtained by differential centrifugation generally contain a mixture of organelles, although nuclei and viral particles can sometimes be purified completely by this procedure.

FIGURE 4-36 Differential centrifugation is a common first step in fractionating a cell homogenate. The homogenate that results from disrupting cells is usually filtered to remove unbroken cells and then centrifuged at a fairly low speed to selectively pellet the nuclei — the largest organelle. The undeposited material (the supernatant) is next centrifuged at a higher speed to sediment the mitochondria, chloroplasts, lysosomes, and peroxisomes. Subsequent centrifugation in an ultracentrifuge at 100,000*g* for 60 minutes results in deposition of the plasma membrane, fragments of the endoplasmic reticulum, and large polyribosomes. The recovery of ribosomal subunits, small polyribosomes, and particles such as complexes of enzymes requires additional centrifugation at still higher speeds. Only the cytosol — the soluble aqueous part of the cytoplasm — remains in the supernatant after centrifugation at 300,000*g* for 2 hours.

An impure organelle fraction obtained by differential centrifugation can be further purified by *equilibrium density-gradient centrifugation*, which separates cellular components according to their density. After the fraction is resuspended, it is layered on top of a solution that contains a gradient of a dense non-ionic substance (e.g., sucrose or glycerol). The tube is centrifuged at a high speed (about 40,000 rpm) for several hours, allowing each particle to migrate to an equilibrium position where the density of the surrounding liquid is equal to the density of the particle (Figure 4-37). The different layers of the gradient are then recovered by pumping out the contents of the centrifuge tube through a narrow piece of tubing and collecting the fractions (see Classic Experiment 4-1).

FIGURE 4-37 A mixed-organelle fraction can be further separated by equilibrium density-gradient centrifugation. In this example, using rat liver, material in the pellet from centrifugation at 15,000*g* (see Figure 4-36) is resuspended and layered on a gradient of increasingly dense sucrose solutions in a centrifuge tube. During centrifugation for several hours, each organelle migrates to its appropriate equilibrium density and remains there. To obtain a good separation of lysosomes from mitochondria, the liver is perfused with a solution containing a small amount of detergent before the tissue is disrupted. During this perfusion period, detergent is taken into the cells by endocytosis and transferred to the lysosomes, making them less dense than they would normally be and permitting a clean separation of lysosomes from mitochondria.

Because each organelle has unique morphological features, the purity of organelle preparations can be assessed by examination in an electron microscope. Alternatively, organelle-specific marker molecules can be quantified. For example, the protein cytochrome *c* is present only in mitochondria, so the presence of this protein in a fraction of lysosomes would indicate its contamination by mitochondria. Similarly, catalase is present only in peroxisomes; acid phosphatase, only in lysosomes; and ribosomes, only in the rough endoplasmic reticulum or the cytosol.

Organelle-Specific Antibodies Are Useful in Preparing Highly Purified Organelles

Cell fractions remaining after differential and equilibrium density-gradient centrifugation usually contain more than one type of organelle. Monoclonal antibodies to various organelle-specific membrane proteins are a powerful tool for further purifying such fractions. One example is the purification of vesicles whose outer surface is covered with the protein **clathrin**; these coated vesicles are derived from coated pits at the plasma membrane during receptor-mediated endocytosis, a topic we will discuss in detail in Chapter 14. An antibody to clathrin, bound to a dead bacterial cell that expressed protein A on its surface, can selectively bind these vesicles in a crude preparation of membranes, and the whole

antibody complex can then be isolated by low-speed centrifugation (Figure 4-38). A related technique uses tiny metallic beads coated with specific antibodies. Organelles that bind to the antibodies, and are thus linked to the metallic beads, are recovered from the preparation by adhesion to a small magnet on the side of the test tube.

FIGURE 4-38 Coated vesicles can be purified by binding to an antibody specific for a vesicle surface protein and linkage to bacterial cells. In this example, a suspension of membranes from rat liver is incubated with an antibody specific for clathrin, a protein that coats the outer surface of certain cytosolic vesicles. To this mixture is added a suspension of killed *Staphylococcus aureus* bacteria, whose surface membrane contains protein A, which binds to the constant (Fc) region of antibodies. (a) Interaction of protein A with antibodies bound to clathrin-coated vesicles links the vesicles to the bacterial cells. The vesicle-bacteria complexes can then be recovered by low-speed centrifugation. (b) A thin-section electron micrograph reveals clathrin-coated vesicles bound to an *S. aureus* cell. See E. Merisko et al., 1982, *J. Cell Biol.* **93**:846.

All cells contain a dozen or more different types of small, membrane-limited vesicles of about the same size (50–100 nm in diameter) and density, which makes them difficult to separate from one another by centrifugation techniques. Immunological techniques are particularly useful for purifying specific classes of such vesicles. Fat and muscle cells, for instance, contain a particular glucose transporter (GLUT4) that is localized to the membrane of one of these vesicle types. When insulin is added to the cells, these vesicles fuse with the plasma membrane and increase the number of glucose transporters able to take up glucose from the blood. As we will see in Chapter 15, this process is critical for maintaining the appropriate concentration of sugar in the blood. The GLUT4-containing vesicles can be purified by using an antibody that binds to a segment of the GLUT4 protein that faces the cytosol. Likewise, the various transport vesicles discussed in Chapter 14 are characterized by unique surface proteins that permit their separation with the aid of specific antibodies.

A variation of this technique is employed when no antibody specific for the organelle under study is available. A gene encoding an organelle-specific membrane protein is modified by the addition of a segment encoding an epitope tag; the tag is placed on a segment of the protein that faces the cytosol. Following stable expression of the recombinant protein in the cell under study, an anti-epitope monoclonal antibody (described above) can be used to rapidly purify the organelle following disruption of the cell.

Proteomics Reveals the Protein Composition of Organelles

We introduced this section by emphasizing how important it is to isolate organelles to identify their components. For many years, the technology was not sufficiently sophisticated to generate a complete inventory of the proteins in each organelle, but recent advances in genomics and mass spectrometry have now made it possible. This approach combines organelle isolation with the proteomics techniques discussed in Chapter 3.

Identifying all the proteins in an organelle requires three steps. First, one has to be able to isolate the organelle to a high degree of purity. Second, one has to have a way to identify all the sequences of the proteins in the organelle. This identification is generally done by digesting all the proteins with a protease such as trypsin, which cleaves all polypeptides at lysine and arginine residues, and then determining the mass and sequence of all the resulting peptides by mass spectrometry. Third, one has to have a genomic sequence to identify the proteins from which all the peptides came. In this way, the proteomes of many organelles have been determined. As one example, a recent proteomic study on mitochondria purified from mouse brain, heart, kidney, and liver revealed 591 mitochondrial proteins, including 163 proteins not previously known to be associated with this organelle. Several proteins were found in mitochondria only from specific cell types. Determining the

functions associated with these newly identified mitochondrial proteins is a major objective of current research on this organelle.

KEY CONCEPTS OF SECTION 4.4

Isolation of Cell Organelles

- Microscopy has revealed a common set of organelles that are present in eukaryotic cells.
- Disruption of cells by vigorous homogenization, sonication, or other techniques releases their organelles. Swelling of cells in a hypotonic solution weakens the plasma membrane, making it easier to rupture.
- Sequential differential centrifugation of a cell homogenate yields fractions of partly purified organelles that differ in mass and density.
- Equilibrium density-gradient centrifugation, which separates cellular components according to their densities, can further purify cell fractions obtained by differential centrifugation.
- Immunological techniques using antibodies against organelle-specific membrane proteins are particularly useful in purifying organelles and vesicles of similar sizes and densities.
- Proteomic analysis can identify all the protein components in a purified organelle, and differences in organelle composition between tissues.

Review the Concepts

1. Both light and electron microscopy are commonly used to visualize cells, cell structures, and the location of specific molecules. Explain why a scientist may choose one or the other microscopy technique for use in research.
2. The magnification possible with any type of microscope is an important property, but its resolution, the ability to distinguish between two very closely apposed objects, is even more critical. Describe why the resolving power of a microscope is more important for seeing finer details than its magnification. What is the formula used to describe the resolution of a microscope lens, and what are the limitations placed on the values in the formula?
3. Why are chemical stains required for visualizing cells and tissues with the basic light microscope? What advantage do fluorescent dyes and fluorescence microscopy provide in comparison to the chemical dyes used to stain specimens for light microscopy? What advantages do confocal and

deconvolution microscopy provide in comparison to conventional fluorescence microscopy?

4. In certain electron microscopy methods, the specimen is not directly imaged. How do these methods provide information about cellular structure, and what types of structures do they visualize? What limitation applies to most forms of electron microscopy?
5. What is the difference between a cell strain, a cell line, and a clone?
6. Explain why the process of cell fusion is necessary to produce monoclonal antibodies used for research.
7. Much of what we know about cell function depends on experiments using specific cells and specific parts (e.g., organelles) of cells. What techniques do scientists commonly use to isolate cells and organelles from complex mixtures, and how do these techniques work?
8. Hoechst 33258 is a chemical dye that binds specifically to DNA in live cells, and when excited by UV light, it fluoresces in the visible spectrum. Name and describe one specific method, employing Hoechst 33258, an investigator would use to isolate fibroblasts in the G_2 phase of the cell cycle from those fibroblasts in interphase.

CHAPTER 5

Fundamental Molecular Genetic Mechanisms

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

Model of DNA Polymerase I from *Escherichia coli* in the process of replicating DNA. The universal mechanism for copying information in DNA is replication by DNA polymerase, a remarkable copying and proofreading machine. The *E. coli* DNA polymerase I shown here can synthesize a complementary copy of the template strand at a rate of about 500 bases per second, making a mistake only once in every 10^5 bases.

OUTLINE

5.1 The Double-Helical Structure of DNA
5.2 DNA Replication
5.3 DNA Repair and Recombination
5.4 Transcription of Protein-Coding Genes and Formation of mRNA
5.5 The Decoding of mRNA by tRNAs
5.6 Stepwise Synthesis of Proteins on Ribosomes
5.7 Viruses: Parasites of the Cellular Genetic System

One of the foundational principles of cell biology is that the cells that make up a multicellular organism are autonomous — each cell carries its own set of genetic instructions for making all of the specific components of cellular structures, cellular catalysts, and molecular machines that make up a functioning cell of a given type. As was described in Chapter 3, the vast majority of these active cellular components are proteins. The specific function of each individual protein is dictated by its sequence of amino acids, the instructions for which are ultimately encoded in the sequence of nucleotides in **deoxyribonucleic acid (DNA)**, the biological information-carrying molecule. One copy of DNA of the human genome encompassing all 23 chromosomes is about 3.3×10^9 nucleotides long and encodes about 20,000 different proteins. In physical terms, one copy of the genome adds up to a thread of DNA that is about one meter in total length, but that is so fine that two complete copies are compacted into the nucleus of *each* of the approximately 4×10^{13} cells in our body. This information, under the control of a complex regulatory network, is then read out to express the appropriate sets of proteins for each of the specific cell types in the body. Thus the basic principle of autonomy of cellular information implies a system of stored and expressed genetic information that is so vast as to defy comprehension. Yet the general rules, as they are now well understood, for how biological information is managed are in fact quite straightforward and are the same in virtually all forms of life. In this chapter, we describe the basic principles for storage, replication, and expression of biological

information. A full understanding of this subject not only requires an understanding of the structure and biochemical properties of the molecules involved, but also requires the application of biological information theory.

Let us first see how information theory can be used to compute the information-carrying capacity of DNA and to compare this to the memory capacity of a computer. Whether in a digital computer or in a biological system, the smallest unit of information is a *bit*, which corresponds to a unit that can have one of two values — in a digital computer these values correspond to 1 and 0. DNA is made up of two complementary strands that can have one of four possible bases (A, G, C, or T) at each position. The information in n bits can specify 2^n possible values; thus each base can be specified by two bits and is therefore said to contain two bits of information. The two strands are base paired with one another according to the principles of base pairing, such that A always pairs with T and G always pairs with C. Because of the fixed rules for base pairing, the sequence of the second complementary strand of DNA is determined by the first and does not add to the information carrying capacity of DNA, but it does add redundancy of information which, as we will see, allows DNA to be readily copied and for damage in DNA to be repaired. Since the human genome contains a total of 3.3×10^9 base pairs, the total information capacity is 6.6×10^9 bits, which corresponds to about 8×10^8 *bytes* of information ($8 \text{ bits} = 1 \text{ byte}$, which is the unit that is used to measure computer memory). A single copy of the

human genome weighs only 3.6×10^{-12} grams and thus on a weight basis, DNA has enormous capacity to store information — in theory, the same information contained in a million one-terabyte laptop computer hard drives could be stored in a mass of DNA the size of a grain of sand.

When cells divide, each daughter cell must receive its own exact copy of the information contained in DNA. DNA is copied or replicated by separation of the two complementary strands of a DNA molecule and then enzymes known as **DNA polymerases** use each strand as a template for the synthesis of two identical copies of the parent molecule by following the rules of base pairing. From the perspective of an information-copying reaction, we are interested in both the rate at which the genome can be copied and the *fidelity* of the reaction, which is related to how frequently errors are produced during copying. From fundamental chemical principles, fidelity is dictated by the difference in energy between a correct and an incorrect base pair in the replication reaction. A typical DNA polymerase incorporates one nucleotide every 2 milliseconds. In this timeframe the theoretical rate of errors in replication would be one mistake in every 10^5 bases, which is the measured fidelity of replication catalyzed by the simplest DNA polymerases. However, if the human genome were replicated with such a low-fidelity polymerase, each parent would pass on about one million new mutations to each of their children. The measured fidelity of DNA replication in humans corresponds to one new mutation in 10^8 bases

per generation. In this chapter, we will see how elaborate proofreading and repair processes have evolved to achieve this 1000-fold enhancement in the fidelity in the replication and transmission of information in DNA.

Gene expression is the mechanism by which the information in the DNA sequence of a gene is used as the instructions for production of a functional protein or RNA molecule. For protein-coding genes, the flow of information within cells follows the outline DNA $\rightarrow$ RNA $\rightarrow$ protein, which is known as the *central dogma* of molecular biology. Before any of the details of how information flows from DNA to proteins were understood, molecular biologists used the basic principles of information theory to deduce how a DNA sequence comprised of four letters (A, G, C, and T) could encode a protein sequence made up of 20 different amino acids. In theory, at least five bits of information (which could give 32 different possibilities) would be required to specify one of 20 amino acids. For a simple code in which blocks of nucleotides in DNA would code for each amino acid, a block size of a least three nucleotides would be required. We now know that the nucleotide sequences of genes are in fact read three nucleotides at a time in blocks known as **codons**. Working out the universal **genetic code** for which amino acid is coded by each of the 64 possible codons was a monumental achievement of twentieth-century science. The genetic code table is the central component of all of the algorithms that are used to

analyze new genomic sequences to deduce the protein sequences that they encode.

The information in the nucleotide sequence of DNA is not translated directly into an amino acid sequence; instead, through the process of **transcription**, the information stored in DNA is copied into a **messenger ribonucleic acid (mRNA)**. Like DNA, RNA carries information in the form of a sequence of four nucleotides, and the process of transcription is similar to replication in that the rules of base pairing are used to synthesize an mRNA of complementary sequence from a DNA template. RNA is generally single stranded and RNA is chemically less stable than DNA. Thus mRNA serves as a temporary copy of the information in a gene that allows the expression of each gene sequence to be controlled independently.

The nucleotide sequence of an mRNA molecule contains information that specifies the correct order of amino acids during the synthesis of a protein. In this process, known as **translation**, the nucleotide sequence of an mRNA molecule is *read* by a second type of RNA called **transfer RNA (tRNA)**. The reading occurs by the base pairing of each of the three nucleotide codons of the mRNA with a complementary anti-codon triplet in the tRNA. The accurate, stepwise assembly of amino acids into proteins takes place in the context of a remarkable macromolecular machine, the **ribosome**, which is composed of a third type of RNA, **ribosomal RNA (rRNA)**, and associated proteins. As the correct amino acids are brought into

sequence by tRNAs, they are linked by peptide bonds to make proteins.

Another type of information that is encoded in DNA is represented by the control sequences that regulate gene expression and determine which genes are on and which are off in each of the cell types in the body. Typically, gene expression is regulated at three possible control points: transcription initiation, mRNA stability, or initiation of translation. Regulation of transcription initiation by the control sequences at a gene promoter and the protein *transcription factors* that interact with them are discussed in Chapter 9. Other types of control sequences that govern the rate at which a given mRNA will be translated or the rate at which the mRNA will be degraded are discussed in Chapter 10.

In this chapter, we first review the chemical and structural properties of DNA that make this molecule ideally suited as the carrier of genetic information in the cell. We next consider the molecular problems involved in DNA replication and the complex cellular machinery that ensures accurate copying of the genetic material. The next section describes how damage to DNA is repaired and how regions of different DNA molecules are exchanged in the process of recombination to generate new combinations of traits in the individual organisms of a species.

In the next several sections, we discuss the basic processes summarized in Figure 5-1: transcription of DNA into mRNA precursors and processing of these precursors to make functional mRNA molecules. After outlining the functions of mRNA, tRNA, and rRNA in protein synthesis, we present a detailed description of these and other components in the biochemical steps of translation.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 5-1 Overview of four basic molecular genetic processes. In this chapter, we cover the three processes that lead to production of proteins (1–3) and the process for replicating DNA (4). During transcription of a protein-coding gene by RNA polymerase (1), the four-base DNA code specifying the amino acid sequence of a protein is copied, or *transcribed*, into a precursor messenger RNA (pre-mRNA) by the polymerization of ribonucleoside triphosphate monomers (rNTPs). Removal of noncoding sequences and other modifications to the pre-mRNA (2), collectively known as *RNA processing*, produce a functional mRNA, which is transported to the cytoplasm. During *translation* (3), the four-

base code of the mRNA is decoded into the 20–amino acid language of proteins. Transfer tRNAs (tRNAs) are the adaptors that read a codon of three nucleotides on the mRNA. In preparation for translation, tRNAs are charged with the correct amino acid by enzymes known as aminoacyl-tRNA synthetases. Ribosomes, the macromolecular machines that translate the mRNA code, are composed of two subunits assembled in the nucleolus from ribosomal RNAs (rRNAs) and multiple proteins (*left*). After transport to the cytoplasm, ribosomal subunits associate with an mRNA and carry out protein synthesis with the help of charged tRNAs and translation factor proteins. During DNA replication (**4**), which occurs only in cells preparing to divide, deoxyribonucleoside triphosphate monomers (dNTPs) are polymerized to yield two identical copies of each chromosomal DNA molecule. Each daughter cell receives one of the identical copies.

The final section of the chapter presents basic information about viruses — parasites that exploit the cellular machinery for DNA replication, transcription, and protein synthesis. In addition to being significant pathogens, viruses are important models for studying these cellular mechanisms of macromolecular synthesis and other cellular processes. Viruses continue to teach us important lessons in molecular cell biology today and have been adapted as experimental tools for introducing genes into cells, tools that are currently being tested for their effectiveness in human gene therapy.

5.1 The Double-Helical Structure of DNA

DNA and RNA have very similar primary structures: both are linear **polymers** composed of only four different nucleotides. Recall from Chapter 2 that all nucleotides consist of an organic base linked to a five-carbon sugar that has a phosphate group attached to the 5′ carbon. Though chemically similar, DNA and RNA polymers in cells have quite different three-dimensional structures. Cellular DNA exists as two long, perfectly complementary, base-paired strands that can be as long as several hundred million nucleotides. Cellular RNAs usually exist as much shorter molecules (RNAs range in length from about 20 to thousands of nucleotides); they are typically single-stranded molecules that may have limited regions that form self-complementary base pairs. As we will see, the relative chemical stability of DNA and its unique redundant complementary structure make DNA an ideal molecule for the stable storage of genetic information.

Native DNA Is a Double Helix of Complementary Antiparallel Strands

The four nucleotides of DNA contain the **purine** bases *adenine* (A) and *guanine* (G) and the **pyrimidine** bases *cytosine* (C) and *thymine* (T) (see Figure 2-17). A single DNA strand has a *backbone* composed

of repeating pentose-phosphate units from which the purine and pyrimidine bases extend as side groups. (Note that the single-letter abbreviations for these bases are also commonly used to denote all the nucleotides in nucleic acid polymers.) Like a polypeptide, a nucleic acid strand has an end-to-end chemical orientation: the $5'$ *end* has a hydroxyl or phosphate group on the $5'$ carbon of its terminal sugar; the $3'$ *end* usually has a hydroxyl group on the $3'$ carbon of its terminal sugar (Figure 5-2). This directionality, plus the fact that synthesis always proceeds $5'$ to $3'$, has given rise to the convention that polynucleotide sequences are written and read in the $5' \rightarrow 3'$ direction (from left to right); for example, the sequence ATG is assumed to be $(5')\mathrm{ATG}(3')$. The chemical linkage between adjacent nucleotides, commonly called a **phosphodiester bond**, actually consists of two phosphoester bonds, one on the $5'$ side of the phosphate and another on the $3'$ side.

FIGURE 5-2 Chemical directionality of a nucleic acid strand. Shown here are alternative representations of a single strand of DNA containing only three bases: cytosine (C), adenine (A), and guanine (G). (a) The chemical structure shows a hydroxyl group at the 3′ end and a phosphate group at the 5′ end. Note also that two phosphoester bonds link adjacent nucleotides; this two-bond linkage is commonly referred to as a *phosphodiester bond*. (b) In the stick diagram (*top*), the sugars are indicated as vertical lines and the phosphodiester bonds as slanting lines; the bases are denoted by their single-letter abbreviations. In the simplest representation

(*bottom*), only the bases are indicated. By convention, a polynucleotide sequence is always written in the $5' \rightarrow 3'$ direction (left to right) unless otherwise indicated.

An understanding of how genetic information might be stored in the nucleotide sequence of DNA began to take shape in 1953 when James D. Watson and Francis H. C. Crick proposed that DNA has a double-helical structure. Their proposal was based on analysis of x-ray diffraction patterns of DNA fibers generated by Rosalind Franklin and Maurice Wilkins, which showed that the structure was helical, and analyses of the base composition of DNA from multiple organisms by Erwin Chargaff and colleagues. Chargaff's studies revealed that while the base composition of DNA (percentages of A, T, G, and C) varies greatly between distantly related organisms, the percentage of A always equals the percentage of T, and the percentage of G always equals the percentage of C, in all organisms. Based on these discoveries and the structures of the four nucleotides, Watson and Crick performed careful molecular model building, proposing a **double helix**, with A always hydrogen-bonded to T and G always hydrogen-bonded to C along the central axis of the double helix, as the structure of DNA.

The most telling feature of the Watson and Crick model was that each of the four possible base pairs fit within the helical backbones in precisely the same manner. Thus any arbitrary sequence of nucleotides can be accommodated by the same double-helical structure. This immediately lead to the understanding that DNA functions as an informational molecule by carrying genetic

information as a sequence of the four letters A, G, C, and T, just as a digital computer memory contains information encoded as a sequence of 1s and 0s. The extraordinary capacity of DNA to carry information stems from the fact that each nucleotide base is only about 50 atoms yet in the context of a DNA sequence can carry two bits of information — while even the most advanced computer memories require many thousands of atoms to store one bit of information.

DNA consists of two associated polynucleotide strands that wind together to form a double helix. The two sugar-phosphate backbones are on the outside of the double helix, and the bases project into the interior. The adjoining bases in each strand stack on top of one another in parallel planes (Figure 5-3a). The orientation of the two strands is *antiparallel;* that is, their $5' \rightarrow 3'$ directions are opposite. The strands are held in precise register by formation of **base pairs** between the two strands: A is paired with T through two hydrogen bonds; G is paired with C through three hydrogen bonds (Figure 5-3b). This base-pair complementarity is a consequence of the size, shape, and chemical composition of the bases. The presence of thousands of such hydrogen bonds in a DNA molecule contributes greatly to the stability of the double helix. Hydrophobic and van der Waals interactions between the stacked adjacent base pairs further stabilize the double-helical structure.

FIGURE 5-3 The DNA double helix. (a) Space-filling model of B DNA, the most common form of DNA in cells. The bases (light shades) project inward from the sugar-phosphate backbones (dark red and blue) of each strand, but their edges are accessible through major and minor grooves. Arrows indicate the $5' \rightarrow 3'$ direction of each strand. Hydrogen bonds between the bases are in the center of the structure. The major and minor grooves are lined by potential hydrogen bond donors and acceptors (highlighted in yellow). (b) Chemical structure of DNA double helix. This extended schematic shows the two sugar-phosphate backbones and hydrogen bonding between the Watson-Crick base pairs, A·T and G·C. See R. E. Dickerson, 1983, *Sci. Am*. **249**:94.

[Part (a) Data from R. Wing et al., 1980, *Nature* **287**:755, PDB ID 1bna.]

In natural DNA, A always hydrogen-bonds with T and G with C, forming A·T and G·C base pairs as shown in Figure 5-4. These associations, always between a larger purine and a smaller pyrimidine, are often called *Watson-Crick base pairs.* Two polynucleotide strands, or regions thereof, in which all the nucleotides form such base pairs are said to be **complementary**. However, in theory and in synthetic DNAs, other base pairs can form. For example, guanine (a purine) could theoretically form hydrogen bonds with thymine (a pyrimidine) within the space available in the helix. Similarly, pairing between adenosine and cytosine could also be accommodated. However, as shown in Figure 5-4, nonstandard G·T and A·C base pairs deviate sufficiently from the precise geometry of natural base pairs to be excluded from double-stranded DNA by the DNA-copying enzyme, as described later in this chapter.

FIGURE 5-4 (a) The structure of the standard A·T and G·C base pairs showing the angle and distance between the bonds connecting the bases to the ribose-phosphate backbone. Because the geometry of the base pairs is almost identical, both of these base pairs are accommodated in the double-helical structure of DNA. (b) Nonstandard base pairs, such as G·T and A·C, have very different bond geometries and are thus excluded from natural DNA by the copying mechanism of DNA polymerase.

Almost all DNA in cells takes the form of a *right-handed* helix. The x-ray diffraction pattern of DNA indicates that the stacked bases are regularly spaced 0.34-nm apart along the helix axis. The helix makes a complete turn every 3.4 to 3.6 nm, depending on the sequence; thus there are about 10–10.5 base pairs per turn. This helical form, referred to as the *B form* of DNA, is the normal form present in most DNA stretches in cells. On the outside of the helix, the spaces

between the intertwined strands form two helical grooves of different widths, described as the *major groove* and the *minor groove* (see Figure 5-3a). As a consequence, the atoms on the edges of each base within these grooves are accessible from outside the helix, forming two types of binding surfaces. DNA-binding proteins can read the sequence of bases in duplex DNA by contacting atoms in either the major or the minor grooves.

Although the atoms facing the surfaces of the major and minor grooves differ between the four bases, the overall structure of the intertwined strands of DNA is uniform regardless of the base sequence. Any irregularities in the DNA caused by chemical damage or mispairing of bases will disrupt this uniform structure and, as we will see in Section 5.3, will allow DNA repair enzymes to identify and act on the site of the damage.

Important modifications in the structure of standard B-form DNA come about as a result of protein binding to specific DNA sequences. Although the multitude of hydrogen and hydrophobic bonds between the bases provides stability to DNA, the double helix is flexible about its long axis. Unlike the α helix in proteins (see Figure 3-4), it has no hydrogen bonds parallel to the axis of the helix. This property allows DNA to bend when complexed with a DNA-binding protein, such as the transcription factor TBP (Figure 5-5). Bending of DNA is also critical to the dense packing of DNA in chromatin, the

protein-DNA complex in which nuclear DNA occurs in eukaryotic cells (see Chapter 8).

FIGURE 5-5 Interaction with a protein such as TBP can bend DNA. The conserved C-terminal domain of the TATA box–binding protein (TBP) binds to the minor groove of specific DNA sequences rich in A and T, untwisting and sharply bending the double helix. Transcription of most eukaryotic genes requires participation of TBP.

[Data from D. B. Nikolov and S. K. Burley, 1997, *Proc. Nat'l. Acad. Sci. USA* **94**:15, PDB ID 1cdw.]

Why did DNA, rather than RNA, evolve to be the carrier of genetic information in cells? The hydrogen at the 2′ position in the deoxyribose of DNA makes it a far more stable molecule than RNA, which instead has a hydroxyl group at the 2′ position of ribose (see Figure 2-16). The 2′-hydroxyl groups in RNA participate in the slow, OH^--catalyzed hydrolysis of phosphodiester bonds at neutral pH (as shown in Figure 5-6). The absence of 2′-hydroxyl groups in DNA prevents this process. Therefore, the presence of deoxyribose in DNA makes it a more stable molecule — a characteristic that is critical to its function in the long-term storage of genetic information.

FIGURE 5-6 Spontaneous hydrolysis of RNA catalyzed by the 2′-hydroxyl group. The 2′-hydroxyl group in RNA can act as a nucleophile, attacking the phosphodiester bond. The 2′,3′ cyclic monophosphate derivative is further hydrolyzed to a mixture of 2′ and 3′ monophosphates. Importantly, this facile mechanism of phosphodiester bond hydrolysis cannot occur in DNA, which lacks 2′-hydroxyl groups.

DNA Can Undergo Reversible Strand Separation

During replication and transcription of DNA, the strands of the double helix must separate to allow the internal edges of the bases to pair with the bases of the nucleotides being polymerized into new complementary polynucleotide chains. In later sections, we describe the cellular mechanisms that separate and subsequently reassociate DNA strands during replication and transcription. Here we discuss the fundamental factors that influence the separation and reassociation of DNA strands. These properties of DNA were elucidated by in vitro experiments.

The unwinding and separation of DNA strands, referred to as **denaturation,** or **melting**, can be induced experimentally by increasing the temperature of a solution of DNA. As the thermal energy increases, the resulting increase in molecular motion eventually breaks the hydrogen bonds and other forces that stabilize the double helix. The strands then separate, driven apart by the electrostatic repulsion of the negatively charged deoxyribose-phosphate backbones of the two strands. Near the denaturation temperature, a small increase in temperature causes a rapid, nearly simultaneous loss of the multiple weak interactions holding the strands together along the entire length of the DNA molecules (Figure 5-7a). The stacked base pairs in duplex DNA absorb less ultraviolet (UV) light than the unstacked bases in single-stranded DNA, and this change leads to an abrupt increase in the absorption of UV light. This phenomenon, known as *hyperchromicity*, is useful for monitoring DNA denaturation.

EXPERIMENTAL FIGURE 5-7 G·C content of DNA affects melting temperature. The temperature at which DNA denatures increases with the proportion of G·C pairs. (a) Melting of double-stranded DNA can be monitored by its absorption of UV light at $260\ \mathrm{nm}$. As regions of double-stranded DNA unpair, the absorption of light by those regions increases almost twofold. The temperature at which half the bases in a double-stranded DNA sample have denatured is denoted T_m (for "temperature of melting"). (b) The T_m is a function of the G·C content of the DNA; the greater the $\mathrm{G} + \mathrm{C}$ percentage, the higher the T_m.

The *melting temperature* (T_m) at which DNA strands separate depends on several factors. Molecules that contain a greater proportion of G·C pairs require higher temperatures to denature because the three hydrogen bonds in G·C pairs make these base pairs more stable than A·T pairs, which have only two hydrogen bonds. Indeed, the percentage of G·C base pairs in a DNA sample can be estimated from its T_m (Figure 5-7b). The ion concentration of the solution also influences the T_m because the negatively charged phosphate groups in the two strands are shielded by positively charged ions. When the ion concentration is low, this shielding is decreased, thus increasing the repulsive forces between the strands and reducing the T_m.

Agents that destabilize hydrogen bonds, such as formamide or urea, also lower the T_m. Finally, extremes of pH denature DNA at low temperatures. At low (acid) pH, the bases become protonated and thus positively charged, repelling each other. At high (alkaline) pH, the bases lose protons and become negatively charged, again repelling each other because of their similar charges. In cells, pH and temperature are, for the most part, maintained at a constant level. These features of DNA denaturation are most useful for manipulating DNA in a laboratory setting.

The single-stranded DNA molecules that result from denaturation form random coils without an organized structure. Lowering the temperature, increasing the ion concentration, or neutralizing the pH causes two complementary strands to reassociate into a perfect double helix. The extent of such *renaturation* is dependent on time, the DNA concentration, and the ion concentration. Two DNA strands that are not related in sequence will remain as random coils and will not renature, but they will not inhibit complementary DNA partner strands from finding each other and renaturing. Denaturation and renaturation of DNA are the basis of nucleic acid **hybridization**, a powerful technique used to study the relatedness of two DNA samples and to detect and isolate specific DNA molecules in a mixture containing numerous different DNA sequences (see Chapter 6).

DNA Molecules Can Acquire Torsional Stress

Many bacterial genomic DNAs and many viral DNAs are circular molecules. Circular DNA molecules also occur in mitochondria, which are present in almost all eukaryotic cells, and in chloroplasts, which are present in plants and some unicellular eukaryotes. Although eukaryotic nuclear DNA is linear, long loops of DNA are fixed in place within chromosomes (see Chapter 8). Each of the two strands in a circular DNA molecule or in a fixed loop of a eukaryotic chromosome forms a closed structure without free ends and is therefore subject to torsional stress.

When DNA is either overwound or underwound, meaning that it has more or fewer helical turns than B-form linear DNA of the same length, the torsional stress thus produced will be relieved by the DNA molecule twisting back on itself forming *supercoils* (Figure 5-8a). A similar topological interconversion between turns and supercoils can be demonstrated by the twists that form in a rubber band after being rolled between your fingertips. As we will see in the next section, when DNA replicates, the two strands must unwind; the remaining portion of the molecule would gain one supercoil for the unwinding of every complete turn of the strands in the double helix, which occurs every 10 base pairs. Since a typical replication fork moves at a rate of about 500 bases per second, supercoils would be introduced into the DNA ahead of the moving replication fork at a

rate of 50 per second. To relieve the torsional stress that would be caused by supercoils developed during replication, all cells contain *topoisomerase I*. This enzyme binds to DNA at random sites and breaks a phosphodiester bond in one strand. Such a one-strand break in DNA is called a *nick*. The broken end then winds around the uncut strand, leading to loss of supercoils (Figure 5-8b). Finally, the same enzyme joins (ligates) the two ends of the broken strand. Another type of enzyme, *topoisomerase II*, relieves torsional stress in DNA by making breaks in both strands of a double-stranded DNA and then religating them.

EXPERIMENTAL FIGURE 5-8 Topoisomerase I relieves torsional stress on DNA. (a) Electron micrograph of SV40 viral DNA. When the circular DNA of the SV40 virus is isolated and separated from its associated protein, the DNA duplex is

underwound and assumes the supercoiled configuration. (b) If a supercoiled DNA is nicked (i.e., one strand cleaved), the strands can rewind, leading to loss of a supercoil. Topoisomerase I catalyzes this reaction and also *reseals* the broken ends. All the supercoils in isolated SV40 DNA can be removed by the sequential action of this enzyme, producing the relaxed-circle conformation. For clarity, the shapes of the molecules at the bottom have been simplified.

KEY CONCEPTS OF SECTION 5.1

The Double-Helical Structure of DNA

- Deoxyribonucleic acid (DNA), the genetic material, is made up of two long, unbranched polymers of nucleotides. A nucleotide consists of a phosphorylated pentose linked to either a purine-adenine (A) or guanine (G), or a pyrimidine-cytosine (C) or thymine (T). Adjacent nucleotides in a polynucleotide are linked by phosphodiester bonds. The entire strand has a chemical directionality with $5'$ and $3'$ ends (see Figure 5-2).
- Natural DNA contains two complementary antiparallel polynucleotide strands wound together into a regular right-handed double helix with the bases on the inside and the two sugar-phosphate backbones on the outside (see Figure 5-3). The double-stranded structure of DNA is significantly stabilized by noncovalent bonds consisting of hydrogen bonds between pairs of bases on opposite strands and by hydrophobic interactions between adjacent base pairs stacked perpendicular to the helix axis.
- The standard Watson-Crick base pairs — G·C and A·T — have nearly identical dimensions and are the only base pairs accommodated by the native double-helical structure.
- Binding of protein to DNA can deform its helical structure, causing local bending or unwinding of the DNA molecule.
- Heat causes the DNA strands to separate (denature). The melting temperature (T_{m}) of DNA increases with the percentage of G·C base pairs. Under suitable conditions, separated complementary nucleic acid strands will renature.
- Overwinding or underwinding of DNA causes long DNA molecules to twist on themselves, forming supercoils (see Figure 5-7). Unwinding of chromosomal DNA during replication would generate a large number of supercoils except that enzymes called *topoisomerases* relieve this torsional stress by removing supercoils from DNA molecules.

5.2 DNA Replication

In a human cell, the genetic information encoded in DNA resides in 23 pairs of chromosomes, with each chromosome consisting of a double-stranded helical molecule hundreds of millions of nucleotides long. When cells divide, each of the two daughter cells must contain exactly the same genetic information as the parent cell. Thus every cell division must be accompanied by the exact copying of the DNA sequence of each chromosome by a process known as DNA replication. A key feature of the double-helical DNA structure that was immediately apparent to Watson and Crick was that the invariant rules for base pairing (A with T and G with C) mean that each strand of a DNA polymer carries the same information in complementary form. The implication was that DNA replication could be achieved by separating the two strands of the DNA polymer and then using each strand as a template in the synthesis of new, complementary strands, thus producing two duplicate, double-stranded copies of the original DNA molecule.

An understanding of the biochemical mechanism for copying of DNA came from the isolation of the first template-directed DNA polymerase enzyme from extracts of *Escherichia coli* cells by Arthur Kornberg and colleagues in 1956. Although we now know that the isolated enzyme known as DNA polymerase I is involved in DNA repair and not the replication of the *E. coli* chromosome, all template-directed DNA polymerases operate by the same

fundamental rules. The lessons learned from studying DNA polymerase I have proved to be universal.

DNA Polymerases Require a Template and a Primer to Replicate DNA

All DNA polymerases have the same requirements for synthesis of a new DNA strand:

i. A single-stranded DNA template.

ii. A DNA **primer** base paired with the template, and with a free hydroxyl group at the 3′ end of the primer to accept a new nucleotide.

iii. A source of deoxyribonucleoside 5′-triphosphate (dNTPs) precursors.

With a primer base-paired to the template strand, a DNA polymerase will add deoxyribonucleotides to the free hydroxyl group at the 3′ end of the primer, as directed by the sequence of the template

strand. The energy for this reaction comes from the release of diphosphate when a phosphoester bond forms between the 3′ oxygen and the α phosphate of the appropriate dNTP. The equilibrium for the reaction is driven further toward chain elongation by pyrophosphatase, an enzyme that catalyzes cleavage of the released PP_i into two molecules of inorganic phosphate (Figure 5-9). After the addition of a nucleotide, a new primer 3′ end will be available to accept the next nucleotide. Polymerization thus proceeds in the 5′ → 3′ direction and will continue until the growing end of the primer reaches the end of the template strand.

FIGURE 5-9 DNA is synthesized $5' \rightarrow 3'$ from dNTP precursors. The three requirements for DNA synthesis are a primer strand with a free $3'$ terminus, a template strand that is base paired to the primer, and a source of deoxyribonucleoside triphosphates (dNTPs). DNA polymerase will act on this substrate to add a new dNTP at the $3'$ end of the primer strand as specified by base pairing between the added base and the template DNA strand. DNA polymerase catalyzes formation of a phosphodiester bond between the $3'$ oxygen of the primer strand and the α phosphate of a correctly base-paired dNTP. New DNA strands are always synthesized in the $5' \rightarrow 3'$ direction and are opposite in polarity to their template DNA strands.

The faithful replication of chromosomal DNA is crucial for life, and DNA polymerases have evolved to replicate DNA with extraordinary speed and fidelity. A typical DNA polymerase can add a single nucleotide to a growing chain in about 2 milliseconds, but this does not give much time for the polymerase to discriminate between a correctly and an incorrectly base-paired nucleotide. If the fidelity of

polymerization was based only on the difference in energy between the correctly and incorrectly hydrogen-bonded nucleotide pair, the polymerase would make at least one mistake every 50 nucleotides. A much higher degree of fidelity is achieved by the active site of the polymerase only accommodating the base pairs with the exact geometry of a normal Watson-Crick base pair while rejecting nonstandard base-pair geometries even if they are only slightly different (see Figure 5-4). By using this type of geometric selection, most polymerases can achieve a fidelity of initial nucleotide incorporation that would produce error rates of about 1 incorrect nucleotide per 10^4 (10,000) polymerized nucleotides.

The fidelity of DNA replication in most organisms is about 1 mistake in 10^9 (one billion) nucleotides incorporated into a growing strand, which is much greater than can be explained by the maximum selectivity of base pairing. This remarkable accuracy is largely due to *proofreading* by DNA polymerases. Proofreading depends on the *$3' \rightarrow 5'$ exonuclease activity* of some DNA polymerases. When an incorrect base is incorporated during DNA synthesis, base pairing between the 3′ nucleotide of the nascent strand and the template strand does not occur. As a result, the polymerase pauses, then transfers the 3′ end of the growing chain to its exonuclease site, where the incorrect mispaired base is removed (Figure 5-10). The 3′ end is then transferred back to the polymerase site, where this region is copied correctly. Most DNA polymerases require a high degree of fidelity and thus have proofreading. For example, all three

E. coli DNA polymerases have proofreading $3' \rightarrow 5'$ exonuclease activity.

FIGURE 5-10 Proofreading by DNA polymerase. All DNA polymerases have a similar three-dimensional structure, which resembles a half-opened right hand. The "fingers" bind the single-stranded segment of the template strand, and the polymerase catalytic activity (Pol) lies in the junction between the fingers and "palm." As long as the correct nucleotides are added to the $3'$ end of the growing strand, it remains in the polymerase site. Incorporation of an incorrect base at the $3'$ end results in a substrate that does not satisfy the requirements for polymerization of the next nucleotide and the polymerase pauses. Because the $3'$ end of the primer strand is not stably base-paired to the template, it is free to move to the $3' \rightarrow 5'$ exonuclease site (Exo) about $3\ \mathrm{nm}$ away, where the mispaired base is removed. Subsequently, the new $3'$ end, now freed of the mispaired nucleotide, can base pair properly with the template and polymerization can resume. See C. M. Joyce and T. T. Steitz, 1995, *J. Bacteriol.* **177**:6321, and S. Bell and T. Baker, 1998, *Cell* **92**:295.

Duplex DNA Is Unwound, and Daughter Strands Are Formed at the DNA Replication Fork

In order for duplex DNA to function as a template during replication, the two intertwined strands must be unwound, or melted, to make their bases available for pairing with the bases of the dNTPs that are polymerized into the newly synthesized daughter strands. This unwinding of the parent DNA strands is performed by enzymes called **helicases**. Unwinding begins at segments in a DNA molecule called *replication origins*, or simply *origins*. The nucleotide sequences of origins from different organisms vary greatly, although they usually contain AT-rich sequences. DNA polymerases cannot initiate replication de novo because, as we have seen, all of these polymerases require a free 3′ primer terminus. However, RNA polymerases that have a similar mechanism to DNA polymerases do have the capability of initiating new strand synthesis from a template without a preexisting primer (see Figure 5-23a). Once helicases have unwound the parent DNA at an origin, a specialized RNA polymerase called **primase** forms a short (~12-nucleotide) RNA primer complementary to the unwound template strands. The primer, still base-paired to its complementary DNA strand, is then elongated by *DNA polymerase α* for another 25 nucleotides or so, forming a primer made of RNA at the 5′ end and DNA at the 3′ end. This primer is further extended by DNA polymerase δ, thereby forming a new daughter strand.

The DNA region at which all these proteins come together to carry out the synthesis of daughter strands is called the **replication fork**. As replication proceeds, the replication fork and the associated

proteins move away from the origin. As noted earlier, local unwinding of duplex DNA produces torsional stress, which is relieved by topoisomerase I. In order for DNA polymerases to move along and copy a duplex DNA, helicase must sequentially unwind the duplex and topoisomerase must remove the supercoils that form.

A major complication in the operation of a DNA replication fork arises from two properties of DNA: the two strands of the parent DNA duplex are antiparallel, and DNA polymerases (like RNA polymerases) can add nucleotides to the growing daughter strands only in the $5' \rightarrow 3'$ direction. Synthesis of one daughter strand, called the **leading strand**, can proceed continuously from a single RNA primer in the $5' \rightarrow 3'$ direction, *the same direction as the movement of the replication fork* (Figure 5-11). The problem comes in the synthesis of the other daughter strand, called the **lagging strand**.

FIGURE 5-11 Leading-strand and lagging-strand DNA synthesis. Nucleotides are added by a DNA polymerase to each growing daughter strand in the $5' \rightarrow 3'$ direction (indicated by arrowheads). The leading strand is synthesized continuously from a single RNA primer (red) at its $5'$ end. The lagging strand is synthesized discontinuously from multiple RNA primers that are formed periodically as each new region of the parent duplex is unwound. Elongation of these primers initially produces Okazaki fragments. As each growing fragment approaches the previous primer, that primer is removed and the fragments are ligated. Repetition of this process eventually results in synthesis of the entire lagging strand.

Because growth of the lagging strand must occur in the $5' \rightarrow 3'$ direction, copying of this strand must proceed in the *opposite* direction from the movement of the replication fork. A cell accomplishes this feat by synthesizing a new primer every 100 to 200 nucleotides on that template strand as more of the strand is exposed by unwinding. Each of these primers, base-paired to the template

strand, is elongated in the $5' \rightarrow 3'$ direction, forming discontinuous segments named **Okazaki fragments** after their discoverer, Reiji Okazaki (see Figure 5-11). The RNA primer of each Okazaki fragment is removed and replaced by DNA chain growth from the neighboring Okazaki fragment; and an enzyme called *DNA ligase* joins the adjacent fragments.

A DNA Replication Fork Advances by Cooperation of Multiple Proteins

Detailed understanding of the eukaryotic proteins that participate in DNA replication initially came from studies with small viral DNAs, particularly the circular genome of SV40, a virus which infects monkeys. Virus-infected cells replicate large numbers of the simple viral genome in a short period of time, which makes them an ideal model system for studying basic aspects of DNA replication. Because simple viruses such as SV40 depend largely on the DNA replication machinery of their host cells (in this case monkey cells), they offer a unique opportunity to study the replication of multiple identical, small DNA molecules by cellular proteins. Figure 5-12 depicts the multiple proteins that coordinate the copying of SV40 DNA at a replication fork. The assembled proteins at a replication fork further illustrate the concept of molecular machines introduced in Chapter 3. These multicomponent complexes permit the cell to

carry out an ordered sequence of events that accomplishes essential cell functions.

FIGURE 5-12 Model of an SV40 DNA replication fork. (a) A hexamer of large T-antigen, a viral protein, functions as a helicase to unwind the parent DNA strands. The leading strand is extended by DNA polymerase ε (Pol ε) up to the replication fork. Pol ε is bound to a ring of PCNA that surrounds the daughter double-stranded DNA so that the Pol ε–PCNA complex remains stably associated with the replication fork. The single-stranded region of the lagging-strand template generated by T-antigen helicase is bound by multiple copies of the heterotrimeric protein RPA. Primers for lagging-strand synthesis (red, RNA; light green, DNA) are synthesized by a complex of primase and DNA polymerase α (Pol α). The 3′ end of each primer synthesized by Pol α–primase is then bound by a PCNA–Pol δ complex, which extends the primer and synthesizes most of each Okazaki fragment. (b) The helicase domain of SV40 T-antigen forms a hexameric replicative helicase. Subunits are shown in alternating light and dark orange. (c) Model of DNA polymerase ε extending the 3′-end of the leading strand. (d) The three subunits of PCNA, shown in different shades of yellow, form a circular structure with a central hole through which daughter double-stranded DNA passes. (e) RFC,

the pentameric “clamp-loader” (monomers shown in different shades of green) is shown bound to a circular trimer PCNA before the PCNA *clamp* is opened. (f) The large subunit of RPA contains two domains that bind single-stranded DNA. Note that the single DNA strand is extended, with the bases oriented in an optimal conformation for replication by Pol δ. See M. O’Donnell, L. Langston, and B. Stillman, 2013, *Cold Spring Harbor Perspect. Biol.* **5**:a010108.

Bochkarev et al., 1997, *Nature* **385**:176, PDB ID 1jmc.]

The molecular machine that replicates SV40 DNA contains only one viral protein; all other proteins involved in SV40 DNA replication are provided by the host cell. This viral protein, *large T-antigen*, forms a hexameric *replicative helicase*, a protein that uses energy from ATP hydrolysis to unwind the parent strands at a replication fork. Primers for the leading and lagging daughter strands are synthesized by a complex of *primase*, which synthesizes a short RNA primer (~12 nucleotides), and DNA polymerase α (Pol α), which extends the RNA primer with deoxyribonucleotides for another 25 nucleotides or so, forming a mixed RNA-DNA primer.

The short RNA-DNA primer is extended by the high fidelity *DNA polymerase δ* (Pol δ), which possess a proofreading mechanism based on $3' \rightarrow 5'$ exonuclease activity. During the replication of cellular DNA, Pol δ synthesizes lagging-strand DNA, while a second high-fidelity polymerase, *DNA polymerase* ε (Pol ε), synthesizes most of the

length of the leading strand. Pol δ and Pol ε each form a complex with *PCNA* (*p*roliferating *c*ell *n*uclear *a*ntigen), which displaces the primase–Pol α complex following primer synthesis. As illustrated in Figure 5-12d, PCNA is a homotrimeric protein that has a central hole through which the daughter duplex DNA passes, thereby preventing the PCNA–Pol δ and PCNA–Pol ε complexes from dissociating from the template. As such, PCNA is known as a *sliding clamp* that enables Pol δ and Pol ε to remain stably associated with a single template strand for thousands of nucleotides. A pentameric protein called *RFC* (*r*eplication *f*actor *C*) functions to open the PCNA ring so that it can encircle the short region of double-stranded DNA synthesized by Pol α. Consequently, RFC is called a *clamp loader*.

After parent DNA is separated into single-stranded templates at the replication fork, the leading strand is extended by Pol ε, which can extend the growing strand up to the replication fork. The single-stranded template for lagging-strand synthesis is bound by multiple copies of RPA (*r*eplication *p*rotein *A*), a heterotrimeric protein (Figure 5-12c). Binding of RPA maintains the template in a uniform conformation that is optimal for copying by Pol δ. Bound RPA proteins are dislodged from the parent strand by Pol δ as it synthesizes the complementary strand base-paired with the parent strand.

Several other eukaryotic proteins that function in DNA replication are not depicted in Figure 5-12. For example, topoisomerase I

associates with the parental double-stranded DNA ahead of the replicative helicase (i.e., to the left of large T-antigen in Figure 5-12) to remove torsional stress introduced by the unwinding of the parent strands (see Figure 5-7a). Ribonuclease H and FEN I remove the ribonucleotides at the 5′ ends of Okazaki fragments; these ribonucleotides are replaced by deoxyribonucleotides added by Pol δ as it extends the upstream Okazaki fragment. Successive Okazaki fragments are coupled by DNA ligase through standard $5' \rightarrow 3'$ phosphoester bonds. Other specialized DNA polymerases are involved in the repair of mismatches and lesions in DNA (see Section 5.3).

DNA Replication Occurs Bidirectionally from Each Origin

As indicated in Figures 5-11 and 5-12, both parent DNA strands that are exposed by local unwinding at a replication fork are copied into daughter strands. In theory, DNA replication from a single origin could involve one replication fork that moves in one direction. Alternatively, two replication forks might assemble at a single origin and then move in opposite directions, leading to *bidirectional growth* of both daughter strands.

We now know that all bacterial, archaeal, and eukaryotic cells employ a bidirectional mechanism of DNA replication. In the case of

SV40 DNA, replication is initiated by the binding of two large T-antigen hexameric helicases to the single SV40 origin and the assembly of other proteins to form two replication forks. These forks then move away from the SV40 origin in opposite directions, and leading- and lagging-strand synthesis occurs at both forks. As shown in Figure 5-13, the left replication fork extends DNA synthesis in the leftward direction; similarly, the right replication fork extends DNA synthesis in the rightward direction.

FIGURE 5-13 Bidirectional mechanism of DNA replication. The left replication fork here is comparable to the replication fork diagrammed in Figure 5-29 (although that figure also shows proteins other than large T-antigen, which are not shown here). *Top:* Two large T-antigen hexameric helicases first bind at the replication origin in opposite orientations. Step **1**: Using energy provided by ATP hydrolysis, the helicases move in opposite directions, unwinding the parent DNA and generating single-stranded templates, which are bound by RPA proteins (not shown). Step **2**: Primase–Pol α complexes synthesize short primers (red) base-paired to each of the separated parent strands. Step **3**: PCNA-Rfc–Pol ε complexes replace the primase–Pol α complexes and extend the short primers, generating the leading strands (dark green) at each replication fork. Step **4**: The helicases further unwind the parent strands, and RPA proteins bind to the newly exposed single-stranded regions. Step **5**: PCNA-Rfc–Pol ε complexes extend the leading strands farther. Step **6**: Primase–Pol α complexes synthesize primers for lagging-strand synthesis at each replication fork. Step **7**: PCNA-Rfc–Pol δ complexes displace the primase–Pol α complexes and extend the lagging-strand Okazaki fragments (light green), which are eventually ligated to the 5′ ends of the leading strands. The position where ligation occurs is represented by a circle. Replication continues by further unwinding of the parent strands and synthesis of leading and lagging strands as in steps **4**–**7**. (Although depicted here as individual steps for clarity, unwinding and synthesis of leading and lagging strands occur concurrently.)

Unlike SV40 DNA, eukaryotic chromosomal DNA molecules contain multiple replication origins separated by tens to hundreds of kilobases. A six-subunit protein called *ORC*, for *o*rigin *r*ecognition *c*omplex, binds to each origin and associates with other proteins required to load cellular hexameric helicases composed of six homologous *MCM* (*m*ini*c*hromosome *m*aintenance) proteins. Two MCM helicases, oriented in opposite directions, separate the parent strands at an origin, and RPA proteins bind to the resulting single-stranded DNA. Synthesis of primers and subsequent steps in the replication of cellular DNA are thought to be analogous to those in SV40 DNA replication (see Figure 5-13).

Cell division begins with the duplication of chromosomes; therefore, the initiation of DNA replication is usually the first step in the cell division cycle. Cellular DNA replication is initiated by activation of MCM helicase by a specific protein kinase (*DDK*), which in turn is regulated by S-phase *cyclin-dependent kinases*. Other cyclin-dependent kinases regulate additional aspects of cell proliferation, including the complex process of mitosis by which a eukaryotic cell divides into two daughter cells. Mitosis and another specialized type of cell division called *meiosis,* which generates haploid sperm and egg cells, is discussed in Chapter 6. We discuss the various regulatory mechanisms that determine the rate of cell division in Chapter 19.

KEY CONCEPTS OF SECTION 5.2

DNA Replication

- DNA polymerases require, as a substrate, a template strand that is base paired to a primer strand with an available $3'$ hydroxyl group. Newly synthesized DNA extends from the primer in the $5' \rightarrow 3'$ direction.
- The high fidelity of DNA replication comes from rigorous geometric constraints for only A·T and G·C base pairs at the polymerase active site, and by a proofreading exonuclease that removes incorrect base pairs.
- Replication begins at a sequence called an *origin*. Each eukaryotic chromosomal DNA molecule contains multiple replication origins. Replication initiates at an origin by unwinding of the DNA and initiation of new synthesis by an RNA polymerases known as primase.
- After initiation replication proceeds from a replication fork, at which one daughter strand (the leading strand) is elongated continuously. The other daughter strand (the lagging strand) is formed discontinuously (see Figure 5-11).
- Discontinuous replication of the lagging strand proceeds by formation of Okazaki fragments synthesized every 100 to 200 nucleotides. The ribonucleotide primers at the $5'$ end of each Okazaki fragment are removed and replaced by elongation from the $3'$ end of the next Okazaki fragment. Finally, adjacent Okazaki fragments are joined by DNA ligase.
- Helicases use energy from ATP hydrolysis to separate the parent (template) DNA strands, which are initially bound by multiple copies of a single-stranded DNA-binding protein, RPA. Primase synthesizes a short RNA primer, which remains base-paired to the template DNA. This primer is initially extended at the $3'$ end by DNA polymerase α (Pol α), resulting in a short daughter strand made up of RNA and DNA.
- Most of the DNA in eukaryotic cells is synthesized by Pol δ and Pol ε, which take over from Pol α and continue elongation of the daughter strands in the $5' \rightarrow 3'$ direction. Pol δ synthesizes most of the length of the lagging strand, while Pol ε synthesizes the leading strand. Pol δ and Pol ε remain stably associated with the template by binding to PCNA, a trimeric protein that encircles the daughter duplex DNA, functioning as a sliding clamp.
- DNA replication generally occurs by a bidirectional mechanism in which two replication forks form at an origin and move in opposite directions, and both template strands are copied at each fork.
- MCM helicases initiate eukaryotic DNA replication in vivo at multiple origins spaced along chromosomal DNA. Synthesis of eukaryotic DNA is regulated by controls on the binding and activity of these helicases.

5.3 DNA Repair and Recombination

Damage to DNA is unavoidable and arises in many ways. DNA damage can be caused by spontaneous cleavage of chemical bonds in DNA, by environmental agents such as ultraviolet and ionizing radiation, and by reaction with genotoxic chemicals that are by-products of normal cellular metabolism or occur in the environment. A change in the normal DNA sequence, called a **mutation**, can occur during replication when a DNA polymerase inserts the wrong nucleotide as it reads a damaged template. Mutations also occur at a low frequency as the result of copying errors introduced by DNA polymerases when they replicate an undamaged template. In humans, mutations that compromise the integrity of the genome can have multiple undesirable consequences. Mutations in the DNA in germ cells will be passed on to offspring, usually with deleterious effects. By contrast, mutations in somatic cells that affect genes that are normally involved in the careful regulation of cell division can cause uncontrolled cell division, eventually leading to tumor formation and cancer. It is thus not surprising that cells have evolved elaborate mechanisms to repair different kinds of damage to the integrity of DNA before the damage becomes fixed as a mutation that is passed to daughter cells.

DNA repair mechanisms take advantage of the inherent redundancy of information contained in complementary strands of DNA and correct the damaged strand using information from the undamaged

strand that is still intact. To accomplish this, most DNA repair processes follow the same general outline. All repair processes must first identify the site of the damage. This is usually done by scanning for disruptions to the regular structure of the DNA helix. Once a lesion is identified, most repair processes then selectively remove a portion of the damaged strand and copy the missing information from the intact complementary strand. In this section, we will review the mechanisms for repair of mismatches between normal bases, repair of chemically altered bases, and repair of broken ends of DNA.

Chemical and Radiation Damage to DNA Can Lead to Mutations

DNA is continually subjected to a barrage of damaging chemical reactions; estimates of the number of DNA-damage events in a single human cell range from 10^4 to 10^6 per day. Even if DNA were not exposed to damaging chemicals, certain aspects of DNA structure are inherently unstable. For example, the bond connecting a purine base to deoxyribose is prone to hydrolysis at a low rate under physiological conditions, leaving a sugar without an attached base. Thus coding information is lost on that strand, and this loss can lead to a mutation during DNA replication. Normal cellular reactions, including the movement of electrons along the electron-transport chain in mitochondria and lipid oxidation in peroxisomes

(see Chapter 12), produce several chemicals that react with and damage DNA, including hydroxyl radicals and superoxide (O_2^-). These chemicals can also cause chemical damage to DNA that can lead to mutations, including mutations that lead to cancers.

Many spontaneous mutations are **point mutations**, which involve a change in a single base pair in the DNA sequence. If a point mutation falls within the protein-coding region of a gene, the mutation may change one codon to another, thus changing the amino acid sequence of the encoded protein. Another possibility is that the mutation may introduce a stop codon in the protein sequence, leading to early termination. Point mutations outside of the coding sequence can also interfere with gene function by, for example, altering the regulation of a gene's transcription, as discussed in Chapter 8. One of the most frequent causes of point mutations is *deamination* of a cytosine (C) base, which converts it into a uracil (U) base. Another is deamination of the common modified base 5-methylcytosine, which forms thymine when it is deaminated. If these alterations are not corrected before the DNA is replicated, the cell will use the strand containing U or T as a template to form a U·A or T·A base pair, thus creating a permanent change in the DNA sequence that is a mutation (Figure 5-14).

FIGURE 5-14 Deamination leads to point mutations. A spontaneous point mutation can be caused by deamination of 5-methylcytosine (C) to form thymine (T). If the resulting T·G base pair is not restored to the normal C·G base pair by base excision-repair mechanisms (step 1), it will lead to a permanent change in sequence (i.e., a mutation) following DNA replication (step 2). After one round of replication, one daughter DNA molecule will have the mutant T·A base pair and the other will have the wild-type C·G base pair.

High-Fidelity DNA Excision-Repair Systems Recognize and Repair Damage

DNA excision-repair systems were first elucidated through a combination of genetic and biochemical studies in *E. coli*. Homologs of the key bacterial proteins exist in eukaryotes from yeasts to

humans, indicating that these error-free mechanisms arose early in evolution to protect DNA integrity. Each of these systems functions in a similar manner: the damaged DNA strand is recognized, a segment of the damaged DNA strand is excised, and the gap is filled by DNA polymerase and ligase using the complementary DNA strand as a template.

Base Excision Repairs T-G Mismatches and Damaged Bases

In humans, the most common type of point mutation is a change from a C to a T, which is caused by deamination of 5-methyl C (see Figure 5-14). The conceptual problem with correcting a lesion in DNA caused by chemically normal bases that are mismatched is in determining which one is the normal and which one is the mutant DNA strand. But since a G·T mismatch is almost invariably caused by chemical conversion of C to U or 5-methyl C to T, the repair system evolved to selectively remove the T and replace it with a C.

The G·T mismatch is recognized by a DNA glycosylase that flips the thymine base out of the helix and then hydrolyzes the bond that connects it to the sugar-phosphate DNA backbone. Following this initial incision, an endonuclease, APE1, cuts the DNA strand near the now abasic site. The deoxyribose phosphate lacking the base is

then removed and replaced with a C by a specialized DNA polymerase that reads the G in the template strand (Figure 5-15).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 5-15 Base excision repair of a T·G mismatch. A DNA glycosylase specific for G·T mismatches, which are usually formed by deamination of 5-methyl C (see Figure 5-34), flips the thymine base out of the helix and then cuts it away from the sugar-phosphate DNA backbone (step 1), leaving just the deoxyribose phosphate (black dot). An endonuclease specific for the resultant abasic site (apurinic endonuclease I, APE1) then cuts the DNA backbone (step 2), and the deoxyribose phosphate is removed by an endonuclease, apurinic lyase (AP lyase) associated with DNA polymerase β, a specialized DNA polymerase used in repair (step 3). The gap is then filled in by DNA Pol β and

sealed by DNA ligase (step **4**, restoring the original G·C base pair. See O. Schärer, 2003, *Angewandte Chemie* **42**:2946.

As mentioned earlier, this repair must take place prior to DNA replication because the incorrect base in this pair, T, occurs naturally in normal DNA. Consequently, it would be able to engage in normal Watson-Crick base pairing during replication, generating a stable point mutation that would no longer be recognized by repair mechanisms (see Figure 5-14, step **2**).

Human cells contain a battery of glycosylases, each of which is specific for a different set of chemically modified DNA bases. For example, one glycosylase removes 8-oxyguanine, an oxidized form of guanine, allowing its replacement by an undamaged G, and others remove bases modified by alkylating agents. The resulting abasic nucleotide is then replaced by the repair mechanism described above. A similar mechanism functions in the repair of lesions resulting from *depurination*, the loss of a guanine or adenine base from DNA caused by hydrolysis of the glycosylic bond between deoxyribose and the base. Depurination occurs spontaneously and is fairly common in mammals and birds because of their warm body temperatures. The resulting abasic sites, if left unrepaired, generate mutations during DNA replication because they cannot specify the appropriate paired base.

Mismatch Excision Repairs Other Mismatches and Small Insertions and Deletions

Another process, also conserved in organisms from bacteria to humans, principally eliminates base-pair mismatches and insertions or deletions of one or a few nucleotides that are accidentally introduced by DNA polymerases during replication. As with base excision repair of a T in a T-G mismatch, the conceptual problem with *mismatch excision repair* is determining which is the normal and which is the mutant DNA strand. In *E. coli*, this discrimination is achieved by preferentially correcting the base in the most recently synthesized strand of DNA which is the most likely to be incorrect. Sensing of the relative age of the two DNA strands takes advantage of a methylation reaction that occurs in the context of double-stranded DNA. Because methylation lags after DNA synthesis, the newly synthesized strand can be identified by it having relatively less methylation. Human cells are also able to discriminate the newly synthesized strand from the template strand immediately after DNA replication. However, this discrimination does not appear to be based on methylation of the DNA, but instead probably involves recognition of the 3′ end of the newly synthesized strand. Once identified, the mispaired segment of the daughter strand — the one with the replication error — is excised and repaired to produce an exact complement of the template strand (Figure 5-

16). In contrast to base excision repair, mismatch excision repair occurs after DNA replication.

FIGURE 5-16 Mismatch excision repair in human cells. The mismatch excision-repair pathway corrects errors introduced during replication. A complex of the MSH2

and MSH6 proteins (bacterial *MutS homologs* 1 and 6) binds to a mispaired segment of DNA in such a way as to distinguish between the template and the newly synthesized daughter strand (step 1). This binding triggers binding of MLH1 and PMS2 (both homologs of bacterial MutL). The resulting DNA-protein complex then binds an endonuclease that cuts the newly synthesized daughter strand. Next a DNA helicase unwinds the helix, and an exonuclease removes several nucleotides from the cut end of the daughter strand, including the mismatched base (step 2). Finally, as with base excision repair, the gap is filled in by a DNA polymerase (Pol δ, in this case) and sealed by DNA ligase (step 3).

Predisposition to a colon cancer known as hereditary nonpolyposis colorectal cancer results from an inherited loss-of-function mutation in one copy of either the *MLH1* or the *MSH2* gene. The MSH1 and MLH2 proteins are essential for DNA mismatch repair (see Figure 5-16). Cells with at least one functional copy of each of these genes exhibit normal mismatch repair. However, tumor cells frequently arise from individual cells that have experienced a random mutation in the second copy; when both copies of one gene have been inactivated, the mismatch repair system is no longer functional. Inactivating mutations in these genes are also common in noninherited forms of colon cancer. ■

Nucleotide Excision Repairs Chemical Adducts That Distort Normal DNA Shape

Cells use *nucleotide excision repair* to fix DNA regions containing chemically modified bases, often called *chemical adducts*, that distort the normal shape of DNA locally. A key to this type of repair is the ability of certain proteins to slide along the surface of a double-stranded DNA molecule looking for bulges or other irregularities in the shape of the double helix. For example, this mechanism repairs *thymine-thymine dimers*, a common type of chemical modification caused by UV light (Figure 5-17); these dimers interfere with both replication and transcription of DNA. Figure 5-18 illustrates how the nucleotide excision-repair system repairs damaged DNA.

FIGURE 5-17 Formation of thymine-thymine dimers. (a) The most common type of DNA damage caused by UV irradiation is the formation of thymine-thymine dimers. (b) These lesions can be repaired by an excision-repair mechanism that recognizes the distortion they

create in the shape of the DNA double helix. The red lines in (b) represent the UV-induced C — C bonds shown in (a).

[Part (b) Data from K. McAteer et al., 1998, *J. Mol Biol*. **282**:1013, PDB ID 1ttd.]

FIGURE 5-18 Nucleotide excision repair in human cells. A DNA lesion that causes distortion of the double helix, such as a thymine-thymine dimer, is initially recognized by a complex of the XP-C (*x*eroderma *p*igmentosum *C* protein) and 23B proteins (step **1**). This complex then recruits transcription factor TFIIH, whose helicase subunits, powered by ATP hydrolysis, partially unwind the double helix. XP-G and RPA proteins then bind to the complex and further unwind and stabilize the helix until a bubble of about 25 bases is formed (step **2**). Then XP-G (now acting as an endonuclease) and XP-F, a second endonuclease, cut the damaged strand at points 24–32 bases apart on each side of the lesion (step **3**). This releases the DNA fragment with the damaged bases, which is degraded to mononucleotides. Finally the gap is filled by DNA polymerase exactly as in DNA replication, and the remaining nick is sealed by DNA ligase (step **4**). See J. Hoeijmakers, 2001, *Nature* **411**:366, and O. Schärer, 2003, *Angewandte Chemie* **42**:2946.

Consider what happens to a thymine-thymine dimer not in the context of a double helix, but in a single strand of DNA at a replication fork. Such an unrepaired lesion of the template would not allow formation of a normal Watson-Crick base pair and the progress of a replicative polymerase would stall. In such events, progress of the replication fork is restored by replacement of the high-fidelity replicative polymerase with a low-fidelity *translesion polymerase*.

A replication fork stalled at an unrepaired thymine-thymine dimer on the template strand, produces a signal that leads to ubiquitylation of the sliding clamp PCNA (see Figure 5-13), which in turn triggers the replacement of a normal replicative polymerase such as Pol δ or Pol ε with the translesion polymerase, Pol η. Pol η has an active site that can accept distorted base pairs and lacks proofreading $3' \rightarrow 5'$ exonuclease activity. These features allow Pol η to form nonstandard base interactions, permitting replication past a thymine-thymine dimer on the template, but also render the polymerase prone to making errors during the replication of normal DNA. After replication has progressed past the lesion, the replication will eventually reset to the normal replicative polymerase. Ultimately, the process of replication past a lesion in the DNA will lead to a segment of DNA in the vicinity of the lesion that is relatively likely to contain mutations caused by errors in replication by translesion polymerase. This explains why mutagenesis with UV light causes a wide variety of base changes in the vicinity of T-T dinucleotides.

Some 30 proteins are involved in the nucleotide excision-repair process, the first of which were identified through a study of the defects in DNA repair in cultured cells from individuals with **xeroderma pigmentosum**, a hereditary disease associated with a predisposition to cancer. Individuals with this disease frequently develop skin cancers called *melanomas* and *squamous cell carcinomas* if their skin is exposed to the UV rays in sunlight. Mutations in any of at least seven different genes, called *XP-A* through *XP-G*, cause

sensitivity to UV by inactivation of components of the nucleotide excision-repair system depicted in Figure 5-18. A second type of xeroderma pigmentosum mutation, which also causes sensitivity to UV rays, called *XP-V,* is in the Pol η gene and prevents replication past UV-induced lesions. ■

Two Systems Use Recombination to Repair Double-Strand Breaks in DNA

Ionizing radiation (e.g., x- and γ-radiation) and some anticancer drugs cause double-strand breaks in DNA. The failure to repair such a lesion would lead to the loss of the portion of the chromosome that was distal to the site of the break and in most cases would be lethal. Two systems have evolved to repair double-strand breaks: breaks can be precisely repaired using information from the intact homologous chromosome by a process of *homologous recombination*, discussed in the next section. Failing precise repair, double-strand breaks can be repaired by the error-prone mechanism of *nonhomologous end joining* (*NHEJ*).

Error-Prone Repair by Nonhomolohous End Joining

In the **nonhomologous end joining** pathway, the free broken ends of DNA are prevented from further degradation by binding to a

complex of two proteins, Ku and DNA-PK. Two Ku and DNA-PK heterodimers bound to DNA can then come together and, with the assistance of additional proteins including DNA ligase, join the ends of two DNA molecules (Figure 5-19). Since diffusion of DNA within the viscous nucleoplasm is fairly slow, the ends of a broken chromosome can often be rejoined before they diffuse apart. Even when correct ends are rejoined, the inevitable action of exonucleases will result in the loss of several base pairs at the joining point. If a deletion resulting from inexact end joining occurs within the coding sequence, the function of the affected gene will likely be lost.

FIGURE 5-19 Nonhomologous end joining. (a) When sister chromatids are not available to help repair double-strand breaks, nucleotide sequences are butted together that were not apposed in the unbroken DNA. These DNA ends are usually from the same chromosome locus and, when linked together, several base pairs are lost. Occasionally, ends from different chromosomes are accidentally joined together. A complex of two proteins, Ku and DNA-dependent protein kinase (DNA-PK), binds to the ends of a double-strand break (step **1**). After formation of a synapse, the ends are further processed by nucleases, resulting in removal of a few bases (step **2**), and the two double-stranded molecules are ligated together (step **3**). As a result, the double-strand break is repaired, but several base pairs at the site of the break are removed. See G. Chu, 1997, *J. Biol. Chem.* **272**:24097; M. Lieber et al., 1997, *Curr. Opin. Genet. Devel.* **7**:99; and D. van Gant et al., 2001, *Nat. Rev. Genet*. **2**:196. (b) Structure of KU70/KU80 bound to a duplex DNA end. The complex is shown in a view down the DNA axis (*left*) and from the side (*right*). KU80 is light green, KU70 dark green, DNA blue.

[Part (b) Data from J. R. Walker, R. A. Corpina, and J. Goldberg, 2001, *Nature* **412**:607, PDB ID 1jey.]

Occasionally, however, broken ends from different chromosomes or far apart on the same chromosome are joined together, leading to gross chromosomal rearrangements that can affect the functioning of genes. For example, incorrect joining could create a hybrid gene that codes for the N-terminal portion of one amino acid sequence fused to the C-terminal portion of a completely different amino acid sequence; or a chromosomal rearrangement could bring the promoter of one gene close to the coding region of another gene, changing the level of expression or cell type in which that gene is expressed. Such translocations may generate chimeric genes that can have drastic effects on normal cell function, such as uncontrollable cell growth, which is the hallmark of cancer.

Homologous Recombination Can Repair DNA Damage and Generate Genetic Diversity

A variety of DNA lesions that are not repaired by the mechanisms discussed earlier can be repaired by mechanisms in which the damaged DNA sequence is copied from an undamaged copy of the same or a highly homologous sequence on the homologous chromosome in diploid organisms or the sister chromosome following DNA replication in haploid and diploid organisms. These mechanisms involve an exchange of strands between separate DNA molecules and hence are referred to as **recombination**.

In addition to providing a mechanism for DNA repair, similar recombination mechanisms generate genetic diversity among the individuals of a species by causing the exchange of large regions of chromosomes between the maternal and paternal pair of homologous chromosomes during *meiosis*, the special type of cell division that generates germ cells (sperm and eggs) (see Figure 6-3). In fact, the exchange of regions of homologous chromosomes, called *crossing over*, is required for proper segregation of chromosomes during the first meiotic cell division. Meiosis and the consequences of generating new combinations of maternal and paternal genes by recombination are discussed further in Chapter 6, and the mechanisms leading to proper segregation of chromosomes during meiosis are discussed in Chapter 19. Here we focus on the

molecular mechanisms of DNA recombination, highlighting the exchange of DNA strands between two recombining DNA molecules.

At one time, homologous recombination was thought to be a minor repair process in human cells. This view changed when it was realized that several human cancers are potentiated by inherited mutations in genes that are essential for homologous recombination repair. For example, some women with an inherited susceptibility to breast cancer have a mutation in one allele of either the *BRCA1* or the *BRCA2* gene, both of which encode proteins participating in this repair process. Loss or inactivation of the second allele inhibits the homologous recombination repair pathway and thus tends to induce cancer in mammary or ovarian epithelial cells. Yeasts can use homologous recombination to repair double-strand breaks induced by γ-irradiation. Isolation and analysis of radiation-sensitive (*RAD*) mutants that are deficient in this repair system facilitated the study of this process. Most of the yeast Rad proteins have homologs in the human genome, and the human and yeast proteins function in an essentially identical fashion.

Repair of a Collapsed Replication Fork

An example of recombinational DNA repair is the repair of a replication fork that has come apart, known as a collapsed replication fork. If a break in the phosphodiester backbone (a nick) of one DNA strand is not repaired before a replication fork passes,

the replicated portions of the daughter chromosomes become separated when the replication helicase reaches the nick in the parent strand because there are no covalent bonds between the two fragments of the parent strand on either side of the nick. This process is called *replication fork collapse* (Figure 5-20, step **1**). If the break in the double-stranded daughter DNA molecule is not repaired, it is generally lethal to at least one daughter cell following cell division because of the loss of genetic information between the break and the end of the chromosome. The recombination process that repairs the resulting double-strand break and regenerates a replication fork involves multiple enzymes and other proteins, only some of which are mentioned here.

FIGURE 5-20 Recombinational repair of a collapsed replication fork. Parent strands are light and dark blue. The leading daughter strand is dark green, and the lagging daughter strand light green. Diagonal lines in step 3 and beyond represent a single phosphodiester bond from the DNA strand of the corresponding color. Small black arrows following step 4 represent cleavage of the phosphodiester bonds at the crossover of DNA strands in the Holliday structure. See the text for a discussion.

The first step in the repair of the double-strand break is exonucleolytic digestion of the strand whose 5′ end is at the broken end of DNA, leaving the strand with the 3′ end at the break single stranded (Figure 5-20, step 2). The lagging nascent strand (light green) base-paired to the unbroken parent strand (dark blue) is ligated to the unreplicated portion of the parent chromosome (light blue), as shown in Figure 5-20, step 2. A protein required for the

next step is RecA in bacteria, or the homologous Rad51 in *Saccharomyces cerevisiae* and other eukaryotes. Multiple RecA/Rad51 molecules bind to the single-stranded DNA and catalyze its hybridization to a perfectly or nearly perfectly complementary sequence in another, homologous, double-stranded DNA molecule. The complementary strand of this target double-stranded DNA (dark blue) is displaced as a single-stranded loop of DNA over the region of hybridization to the invading strand (Figure 5-20, step **3**). This RecA/Rad51–catalyzed *invasion* of a duplex DNA by a single-stranded complement of one of the strands is key to the recombination process. This process is called **strand invasion**, and because there is no change in the number of base pairs, it does not require an input of energy.

Next the hybrid region between target DNA and the invading strand is extended away from the break by a process called branch migration (Figure 5-20, step **4**). In this diagram, the diagonal lines represent only one phosphodiester bond. Molecular modeling and other studies show that the first base on either side of the branch is base-paired to a complementary nucleotide. As this branch *migrates* to the left, the number of base pairs remains constant; one new base pair formed with the invading strand (dark green) is matched by the loss of one base pair with the parent strand (blue).

When the hybrid region extends beyond the 5′ end of the broken strand that was digested by the 5′-exonuclease in step **2** (light

blue), the single-stranded parent DNA thus generated (light blue) can base-pair with the complementary region of the other parent strand (dark blue), which becomes single-stranded as the branch migrates to the left (see Figure 5-20, step **4**). The resulting structure is called a **Holliday structure**, after Robin Holliday, the geneticist who first proposed it as an intermediate in genetic recombination. Again, the diagonal lines in the diagram following step **4** represent single phosphodiester bonds, and all bases in the Holliday structure are base-paired to complementary bases in the parent strands. Cleavage of the phosphodiester bonds that *cross over* from one parent strand to the other (step **5**) and ligation of the 5′ and 3′ ends base-paired to the same parent strands (step **6**) result in the generation of a structure similar to a replication fork. Rebinding of replication fork proteins results in extension of the leading strand past the point of the original strand break and re-initiation of lagging-strand synthesis (step **7**), thus regenerating a replication fork. The overall process allows the ligated upper strand in the lower molecule following step **2** to serve as a template for extension of the leading strand in step **7**.

Repair of a Double-Strand Break by Homologous Recombination

A similar mechanism, called **homologous recombination**, can repair a double-strand break in a chromosome and can also exchange large segments of two double-stranded DNA molecules

(Figure 5-21). First, the broken ends of the DNA molecule are digested by 5′-exonucleases, leaving a single-stranded region of DNA with a 3′ end (step **1**). RecA in bacteria or Rad51 in eukaryotes then catalyzes invasion of one of these 3′ ends into the homologous region of the homologous chromosome, as described above for repair of a collapsed replication fork (step **2**). The 3′ end of the invading DNA strand is then extended by a DNA polymerase, displacing the parent strand as an enlarging single-stranded loop of DNA (dark blue) (step **3**). When the loop extends to a sequence that is complementary to the other broken and 5′-exonuclease–digested end of DNA (the fragment on the left following step **1**), the complementary sequences base-pair (diagram following step **3**). This 3′ end is then extended by a DNA polymerase using the displaced single-stranded loop of parent DNA (dark blue) as a template (step **4**).

FIGURE 5-21 Repair of a double-strand break by homologous recombination. For simplicity, each DNA double helix is represented by two

parallel lines with the polarities of the strands indicated by arrowheads at their $3'$ ends. The upper molecule has a double-strand break. Note that in the diagram of the upper DNA molecule, the strand with its $3'$ end at the right is on the top, while in the diagram of the lower DNA molecule, this strand is drawn on the bottom. See the text for discussion. See T. L. Orr-Weaver and J. W. Szostak, 1985, *Microbiol. Rev.* **49**:33.

Next the new $3'$ ends are ligated (step **5**) to the exonuclease-digested $5'$ ends. This generates two Holliday structures in the paired molecules (step **5**). Branch migration of these Holliday structures can occur in either direction (not diagrammed). Finally, cleavage of the strands at the positions shown by the arrows, and ligation of the alternative $5'$ and $3'$ ends at each cleaved Holliday structure, generates two *recombinant* chromosomes that contain the DNA of one *parent* DNA molecule on one side of the initial break point (light and dark green strands), and the DNA of the other parent DNA molecule on the other side of the break point (light and dark blue) (step **6**). The region in the immediate vicinity of the initial break point forms a *heteroduplex*, in which one strand from one parent is base-paired to the complementary strand of the other parent (light or dark green strand base-paired to light or dark blue strand). Base-pair mismatches between the two parent strands are usually repaired by the repair mechanisms discussed above to generate a complementary base pair. In the process, sequence differences between the two parents are lost, a process referred to as **gene conversion**.

Figure 5-22 diagrams how cleavage of one or the other pair of strands at the four-way strand junction in the Holliday structure generates parent or recombinant molecules. This process, called *resolution* of the Holliday structure, separates DNA molecules initially joined by RecA/Rad51–catalyzed strand invasion. Each Holliday structure in the intermediate following Figure 5-21, step **5**, can be cleaved and religated in the two possible ways shown by the two sets of small black arrows in Figure 5-22 (step **1** or step **2**). Consequently, there are four possible products of the recombination process shown in Figure 5-21. After ligation of the cleaved ends, two of these products regenerate the parent chromosomes, with the exception of the heteroduplex region at the break point, which is repaired into the sequence of one parent or the other by a process known as gene conversion. The other two possible products generate recombinant chromosomes as shown in Figure 5-21.

FIGURE 5-22 Alternative resolution of a Holliday structure. Diagonal and vertical lines represent a single phosphodiester bond. It is simplest to diagram the process by rotating the diagram of the bottom molecule 180° so that the top and bottom molecules have the same strand orientations. Cutting the bonds as shown in step **1** and ligating the ends as

indicated regenerates the original chromosomes. Cutting the strands as shown in step 2 and religating as shown at the bottom generates recombinant chromosomes.

KEY CONCEPTS OF SECTION 5.3

DNA Repair and Recombination

- Changes in the DNA sequence result from copying errors and the effects of various physical and chemical agents.
- Eukaryotic cells have three excision-repair systems for correcting mispaired bases and for removing chemical adducts from DNA. Base excision repair, mismatch repair, and nucleotide-excision repair operate with high accuracy and generally do not introduce errors.
- Damaged DNA bases in single-stranded template DNA at a replication fork will block the progress of a replicative DNA polymerase. These blocks can be overcome by a translesion polymerase that has relaxed requirements for proper base pairing during replication. Translesion polymerases are error prone and tend to generate mutations of their own in the vicinity of the original lesion.
- Repair of double-strand breaks by the nonhomologous end joining pathway can link segments of DNA from different chromosomes, possibly forming an oncogenic chromosomal translocation. This repair mechanism also produces a small deletion, even when segments from the same chromosome are joined.
- Error-free repair of double-strand breaks in DNA is accomplished by homologous recombination using the undamaged sister chromatid as a template.
- Inherited defects in the nucleotide excision-repair pathway, as in individuals with xeroderma pigmentosum, predispose them to skin cancer. Inherited colon cancer is frequently associated with mutant forms of proteins essential for the mismatch repair pathway. Defects in repair by homologous recombination are associated with inheritance of one mutant allele of the *BRCA1* or *BRCA2* gene and result in predisposition to breast and uterine cancer.

5.4 Transcription of Protein-Coding Genes and Formation of mRNA

The simplest definition of a *gene* is a unit of DNA that contains the information to specify synthesis of a single polypeptide chain or functional RNA (such as a tRNA). The DNA molecules of small viruses contain only a few genes, whereas the single DNA molecule in each of the chromosomes of higher animals and plants may contain several thousand genes. The vast majority of genes carry information used to build protein molecules, and it is the RNA copies of such *protein-coding genes* that constitute the mRNA molecules of cells.

In its most elemental form, the process of transcription is the formation of an RNA copy of the information carried in DNA for one gene. RNA synthesis, catalyzed by an RNA polymerase and based on the same base-pairing mechanism as DNA replication copies, or *transcribes*, the four-base language of DNA containing A, G, C, and T into the four-base language of RNA, which is identical except that U replaces T. Because of the inherent instability of RNA within the cell, the amount of transcribed RNA can readily be regulated by alterations in the rate of transcription initiation. This allows distinct sets of genes to be expressed in the multiple different types of cells that make up a multicellular organism. Regulation of transcription is addressed in Chapter 8.

For protein encoding genes, the product of transcription is an mRNA, which is subsequently *translated* into the 20–amino acid language of proteins. In this section, we focus on the formation of functional mRNAs from protein-coding genes (see Figure 5-1, step **1**). A similar process yields precursors of rRNAs and tRNAs, encoded by rRNA and tRNA genes; these precursors are then further modified to yield functional rRNAs and tRNAs (see Chapters 8 and 9).

A Template DNA Strand Is Transcribed into a Complementary RNA Strand by RNA Polymerase

The process of transcription is closely related to that of DNA replication, in which one DNA strand acts as a *template* and, in the case of transcription, determines the order in which ribonucleoside triphosphate (rNTP) monomers are linked together to form a complementary RNA chain. Incoming rNTPs base-pair with complementary bases in the template DNA strand, and are then joined to a growing RNA strand in a polymerization reaction catalyzed by **RNA polymerase**. The polymerization reaction involves a nucleophilic attack by the 3′ oxygen in the growing RNA chain on the α phosphate of the next nucleotide precursor to be added, which results in the formation of a phosphodiester bond and the release of

pyrophosphate (PP_i). As with DNA replication, RNA molecules are always synthesized in the $5' \rightarrow 3'$ direction (Figure 5-23a).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 5-23 RNA is synthesized $5' \rightarrow 3'$. (a) Polymerization of ribonucleotides by RNA polymerase during transcription. The ribonucleotide to be added at the $3'$ end of a growing RNA strand is specified by base pairing between the next base in the template DNA strand and the complementary incoming ribonucleoside triphosphate (rNTP). A phosphodiester bond is formed when RNA polymerase catalyzes a reaction between the $3'$ oxygen of the growing strand and the α phosphate of a correctly base-paired rNTP. RNA strands are always synthesized in the $5' \rightarrow 3'$ direction and are opposite in polarity to their template DNA strands. (b) The DNA nucleotide where RNA polymerase begins transcription is designated $+1$. The direction the polymerase travels on the DNA is termed *downstream*, and downstream bases are marked with positive numbers. The opposite direction is termed *upstream*, and upstream bases are marked with negative numbers. Some important gene features lie upstream of the transcription start site, including the promoter sequence that localizes RNA polymerase to the gene. (c) The DNA strand that is being transcribed is the template strand; its complement is the nontemplate strand. The RNA being synthesized is complementary to the template strand and is therefore identical with the nontemplate strand sequence, except with uracil in place of thymine.

By convention, the site on the DNA template at which RNA polymerase begins transcription is numbered $+1$ (Figure 5-23b). *Downstream* denotes the direction in which a template DNA strand is transcribed; *upstream* denotes the opposite direction. Nucleotide positions in the DNA sequence downstream from a start site are indicated by a positive (+) sign; those upstream, by a negative (−) sign. Because RNA is synthesized $5' \rightarrow 3'$, RNA polymerase moves down the template DNA strand in a $3' \rightarrow 5'$ direction. The newly synthesized RNA is complementary to the template DNA strand; therefore, it is identical to the nontemplate DNA strand, with uracil in place of thymine (Figure 5-23c).

Stages in Transcription

To carry out transcription, RNA polymerase performs several distinct functions, as depicted in Figure 5-24. During transcription *initiation*, RNA polymerase, with the help of initiation factors (called s-factors in bacteria and general transcription factors in eukaryotes), recognizes and binds to a specific sequence of double-stranded DNA called a **promoter** (step **1**). After binding, RNA polymerase and the initiation factors separate the DNA strands to make the bases in the template strand available for base pairing with the bases of the rNTPs that the RNA polymerase will polymerize (step **2**). Approximately 12–14 base pairs of DNA around the transcription start site are separated, which allows the template strand to enter the active site of the enzyme. The *active site* is where catalysis of phosphodiester bond formation between rNTPs that are complementary to the template strand takes place. The 12–14 base-pair region of melted DNA in the active site of the polymerase is known as the *transcription bubble*. Transcription initiation is considered complete when the first two ribonucleotides of an RNA chain are linked by a phosphodiester bond (step **3**).

FIGURE 5-24 Three stages in transcription. During initiation of transcription, RNA polymerase forms a transcription bubble and begins polymerization of ribonucleotides (rNTPs) at the start site, which is located within the promoter region. Once a DNA region has been transcribed, the separated strands reassociate into a double helix. The nascent RNA is displaced from its template

strand except at its 3′ end. The 5′ end of the RNA strand exits the RNA polymerase through a channel in the enzyme. Termination occurs when the polymerase encounters a specific termination sequence (stop site). See the text for details. For simplicity, the diagram depicts transcription of four turns of the DNA helix encoding some 40 nucleotides of RNA. Most RNAs are considerably longer, requiring transcription of a longer region of DNA.

After several ribonucleotides have been polymerized, RNA polymerase dissociates from both the promoter DNA and the initiation factors (called σ-*factors* in bacteria, and *general transcription factors* in archaea and eukaryotes). During the *strand elongation* stage, RNA polymerase moves along the template DNA, opening the double-stranded DNA in front of its direction of movement and guiding the strands back together so that they reassociate at the upstream end of the transcription bubble (step **4**). One ribonucleotide at a time is added by the polymerase to the 3′ end of the growing (*nascent*) RNA chain. During strand elongation, the enzyme maintains a melted region of approximately 14–20 base pairs in the transcription bubble. Approximately eight nucleotides at the 3′ end of the growing RNA strand remain base-paired to the template DNA strand in the transcription bubble. The *elongation complex*, comprising RNA polymerase, template DNA, and the nascent RNA strand, can be extraordinarily stable. For example, RNA polymerase transcribes the longest known mammalian gene, containing about 2 million base pairs, without dissociating from the DNA template or releasing the nascent RNA. RNA synthesis occurs at a rate of about 1000–2000 nucleotides per minute, so the

elongation complex must remain intact for more than 24 hours to ensure continuous synthesis of pre-mRNA from this very long gene. Note that although biochemically similar to DNA replication, transcription of RNA occurs about 30 times more slowly in terms of the rate of nucleotides added.

During transcription *termination*, the final stage in RNA synthesis, the completed RNA molecule is released from the RNA polymerase and the polymerase dissociates from the template DNA (step **5**). Once it is released, an RNA polymerase is free to transcribe the same gene again or another gene.

Structure of RNA Polymerases

The RNA polymerases of bacteria, archaea, and eukaryotic cells are fundamentally similar in structure and function. Bacterial RNA polymerases are composed of two related large subunits (β' and β), two copies of a smaller subunit (α), and one copy of a fifth subunit (ω) that is not essential for transcription or cell viability, but that stabilizes the enzyme and assists in the assembly of its subunits. Archaeal and eukaryotic RNA polymerases have several additional small subunits associated with this core complex, which we describe in Chapter 8. Schematic diagrams of the transcription process generally show RNA polymerase bound to an unbent DNA molecule, as in Figure 5-24. However, x-ray crystallography and other studies

of an elongating bacterial RNA polymerase indicate that the DNA bends at the transcription bubble (Figure 5-25).

FIGURE 5-25 Bacterial RNA polymerase. This structure corresponds to the polymerase molecule in the elongation stage of transcription. In this diagram, transcription is proceeding in the rightward direction. Arrows indicate where downstream DNA enters the polymerase and upstream DNA exits at an angle from the downstream DNA. The template strand is light violet; the nontemplate strand, dark violet; the nascent RNA, red. The RNA polymerase β′ subunit is gold; the β subunit, light yellow; and the α subunits visible from this angle, brown. Nucleotides

complementary to the template DNA are added to the $3'$ end of the nascent RNA strand on the right side of the transcription bubble. The newly synthesized nascent RNA exits the polymerase at the upstream side through a channel formed by the β subunit. The ω subunit is also visible from this angle.

Eukaryotic Precursor mRNAs Are Processed to Form Functional mRNAs

Early research on the structure of eukaryotic genes involved studies of viruses that infect animals. When researchers analyzed the regions of a viral DNA molecule that encode viral mRNAs, they were surprised to observe that the sequence of a single viral mRNA was encoded in several regions of the viral DNA separated by DNA sequences that are not present in the mRNA. Later, the development of gene cloning and DNA sequencing (see Chapter 6) allowed researchers to compare the genomic DNA sequences of multicellular organisms with the sequences of their mRNAs. This research revealed that most cellular mRNAs are also encoded in several separate regions of genomic DNA, called *exons*, separated by sequences of DNA called *introns*. Further studies showed that a gene is first transcribed into a long primary transcript that includes both the exon sequences and the intron sequences that separate them. Subsequently, the introns are removed and the exons are spliced together (see Chapter 9). Although introns are common in

multicellular eukaryotes, they are extremely rare in bacteria and archaea and uncommon in many unicellular eukaryotes, such as baker's yeast.

In eukaryotic cells, the site of RNA synthesis — the nucleus — is separated from the site of translation — the cytoplasm. In the nucleus, the primary transcripts of protein-coding genes — **precursor mRNAs (pre-mRNAs)** — must undergo several modifications, collectively termed *RNA processing*, to yield a functional mRNA (see Figure 5-1, step 2). This mRNA must then be exported to the cytoplasm before it can be translated into protein. Thus transcription and translation cannot occur concurrently in eukaryotic cells.

All eukaryotic pre-mRNAs are initially modified at the two ends, and these modifications are retained in mRNAs. As the 5′ end of a nascent RNA chain emerges from the surface of RNA polymerase, it is immediately acted on by several enzymes that together synthesize the *5′ cap*, a 7-methylguanylate that is connected to the terminal nucleotide of the RNA by an unusual 5′, 5′ triphosphate linkage (Figure 5-26). The cap protects an mRNA from enzymatic degradation and assists in its export to the cytoplasm, where it is bound by a protein factor required to begin translation.

7-Methylguanylate

n and Company

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freema

FIGURE 5-26 Structure of the 5′ methylated cap. The distinguishing chemical features of the 5′ methylated cap on eukaryotic mRNA are (1) the 5′ → 5′ linkage of

7-methylguanylate to the initial nucleotide of the mRNA molecule and (2) the methyl group on the 2′ hydroxyl of the ribose of the first nucleotide (base 1). Both of these features occur in all animal cells and in cells of higher plants; yeasts lack the methyl group on nucleotide 1. The ribose of the second nucleotide (base 2) is also methylated in vertebrates. See A. J. Shatkin, 1976, *Cell* **9**:645.

Processing at the 3′ end of a pre-mRNA involves cleavage by an endonuclease to yield a free 3′-hydroxyl group, to which a string of adenylic acid residues is added one at a time by an enzyme called *poly(A) polymerase.* The resulting *poly(A) tail* contains 100–250 bases, and is shorter in yeasts and invertebrates than in vertebrates. Poly(A) polymerase is part of a complex of proteins that can locate and cleave a transcript at a specific site and then add the correct number of A bases, in a process that does not require a template. As discussed further in Section 5.6 and in Chapter 10, the poly(A) tail has important functions both in translation of mRNA and in stabilizing pre-mRNAs in the nucleus and fully processed mRNAs in the nucleus and cytoplasm.

Another step in the processing of many different eukaryotic mRNA molecules is **RNA splicing**: the internal cleavage of a transcript to excise the introns and stitch together the coding exons. Figure 5-27 summarizes the basic steps in eukaryotic mRNA processing, using the β-globin gene as an example. We examine the cellular machinery for carrying out processing of mRNA, as well as tRNA and rRNA, in Chapter 9.

FIGURE 5-27 Overview of RNA processing. RNA processing produces functional mRNA in eukaryotes. The β-globin gene contains three protein-coding exons (constituting the coding region) and two intervening noncoding introns. The introns interrupt the protein-coding sequence between the codons for amino acids 31 and 32 and 105 and 106. Transcription of eukaryotic protein-coding genes starts before the sequence that encodes the first amino acid and extends beyond the sequence that encodes the last amino acid, resulting in noncoding regions at the ends of the primary transcript. These untranslated regions (UTRs) are retained during processing. The $5'$ cap $(\mathrm{m^7Gppp})$ is added during formation of the primary RNA transcript, which extends beyond the poly(A) site. After cleavage at the poly(A) site and addition of multiple A residues to the $3'$

end, splicing removes the introns and joins the exons. The small numbers refer to positions in the 147–amino acid sequence of β-globin.

The functional eukaryotic mRNAs produced by RNA processing retain noncoding regions, referred to as *untranslated regions (UTRs)*, at each end. In mammalian mRNAs, the 5′ UTR may be 100 or more nucleotides long, and the 3′ UTR may be several kilobases in length. Bacterial mRNAs also usually have 5′ and 3′ UTRs, but these regions are much shorter than those in eukaryotic mRNAs, generally containing fewer than 10 nucleotides. As discussed in Chapter 9, the 5′ UTR and 3′ UTR sequences participate in regulation of mRNA translation and stability, and 3′ UTRs also function in the localization of many mRNAs to specific regions of the cytoplasm.

Alternative RNA Splicing Increases the Number of Proteins That Can Be Expressed from a Single Eukaryotic Gene

The vast majority of genes in multicellular eukaryotes are made up of multiple exons separated by introns. As noted in Chapter 3, many proteins from higher eukaryotes have a multidomain tertiary structure (see Figure 3-10) and it is often the case that the boundaries between protein domains correspond to junctions

between exons of the underlying gene. This tendency for exons to correspond to discrete folded domains in the encoded protein suggests that many eukaryotic proteins have evolved by genetic recombination events that bring exons together in new combinations, a process known as exon shuffling.

We will see many examples throughout this book of mammalian proteins that contain multiple repeated copies of a protein domain with identical or nearly identical amino acid sequences. Evidently these sequences arose by recombination events that led to a string of multiple copies of the same exon separated by introns. The presence of multiple intron genes permits expression of multiple variations of the protein from a single gene by means of **alternative splicing**. In higher eukaryotes, alternative splicing is an important mechanism for production of different forms of a protein, called **isoforms**, by different types of cells.

Fibronectin, a multidomain protein found in mammals, provides a good example of alternative splicing (Figure 5-28). Fibronectin is a long, adhesive protein secreted into the extracellular space that can bind other proteins together. What and where it binds depends on which domains are spliced together. The fibronectin gene contains numerous exons, grouped into several regions corresponding to specific domains of the protein. Fibroblasts produce fibronectin mRNAs that contain exons EIIIA and EIIIB; these exons encode a protein domain that binds tightly to proteins in the fibroblast plasma membrane. Consequently, this fibronectin isoform adheres

fibroblasts to the extracellular matrix. Alternative splicing of the fibronectin primary transcript in hepatocytes, the major type of cell in the liver, yields mRNAs that lack the EIIIA and EIIIB exons. As a result, the fibronectin secreted by hepatocytes into the blood does not adhere tightly to fibroblasts or to most other cell types, which allows it to circulate. During formation of blood clots, however, other fibrin-binding domains of hepatocyte fibronectin bind to fibrin, one of the principal constituents of blood clots. Yet another domain of the bound fibronectin then interacts with integrins on the membranes of passing platelets, thereby expanding the clot by addition of platelets.

FIGURE 5-28 Alternative splicing. The ~75-kb fibronectin gene (*top*) contains multiple exons; splicing of the fibronectin transcript varies by cell type. The EIIIB and EIIIA exons (green) encode binding domains for specific proteins on the surface of fibroblasts. The fibronectin mRNA produced in fibroblasts includes the EIIIA and EIIIB exons, whereas these exons are spliced out of fibronectin mRNA in hepatocytes. In this diagram, introns (black lines in the top diagram of the fibronectin gene) are not drawn to scale; most of them are much longer than any of the exons.

More than 20 different isoforms of fibronectin have been identified, each encoded by a different, alternatively spliced mRNA composed of a unique combination of fibronectin gene exons. Sequencing of

large numbers of mRNAs isolated from various tissues and comparison of their sequences with genomic DNA has revealed that nearly 90 percent of all human genes are expressed as alternatively spliced mRNAs. Clearly alternative RNA splicing greatly expands the number of protein variants encoded by the genomes of higher, multicellular organisms.

KEY CONCEPTS OF SECTION 5.4

Transcription of Protein-Coding Genes and Formation of mRNA

- Transcription of DNA is carried out by RNA polymerase, which adds one ribonucleotide at a time to the $3'$ end of a growing RNA chain (see Figure 5-23). The sequence of the template DNA strand determines the order in which ribonucleotides are polymerized to form an RNA chain.
- During transcription initiation, RNA polymerase binds to a specific site in DNA (the promoter), locally melts the double-stranded DNA to reveal the unpaired template strand, and polymerizes the first two nucleotides complementary to the template strand. The melted region of 12–14 base pairs is known as the transcription bubble.
- During strand elongation, RNA polymerase moves down the DNA, melting the DNA ahead of the polymerase so that the template strand can enter the active site of the enzyme, and allowing the complementary strands of the region just transcribed to reanneal behind it. The transcription bubble moves with the polymerase as the enzyme adds ribonucleotides complementary to the template strand to the $3'$ end of the growing RNA chain.
- When RNA polymerase reaches a termination sequence in the DNA, the enzyme stops transcription, leading to release of the completed RNA and dissociation of the enzyme from the template DNA.
- In eukaryotic DNA, each protein-coding gene is transcribed from its own promoter. The initial primary transcript very often contains noncoding regions (introns) interspersed with coding regions (exons).
- Eukaryotic primary transcripts must undergo RNA processing to yield functional RNAs. During processing, the ends of nearly all primary transcripts from protein-coding

genes are modified by addition of a $5'$ cap and $3'$ poly(A) tail. Transcripts from genes containing introns undergo splicing, the removal of the introns and joining of the exons (see Figure 5-27).

- The individual domains of multidomain proteins found in higher eukaryotes are often encoded by individual exons or a small number of exons. Distinct isoforms of such proteins are often expressed in specific cell types as the result of alternative splicing of exons.

5.5 The Decoding of mRNA by tRNAs

As we saw in Chapter 3, the linear order of amino acids in each protein determines its three-dimensional structure and activity. Translation is the whole process by which the nucleotide sequence of an mRNA is used as a template to join the amino acids of a polypeptide chain in the correct order (see Figure 5-1, step **3**). In eukaryotic cells, protein synthesis occurs in the cytoplasm, where three types of RNA molecules come together to perform different but cooperative functions (Figure 5-29):

1. **Messenger RNA (mRNA)** carries the genetic information transcribed from DNA in a linear form. The mRNA is read in sets of three-nucleotide sequences, called **codons**, each of which specifies a particular amino acid.
2. **Transfer RNA (tRNA)** is the key to deciphering the codons in mRNA and serves as an adaptor to link three bases of RNA sequence to a particular amino acid. Each type of amino acid has its own subset of tRNAs, which are covalently bound to that amino acid and carry it to the growing end of a polypeptide chain when the next codon in the mRNA calls for it. The correct tRNA with its attached amino acid is selected at each step because each specific tRNA molecule contains a three-nucleotide sequence, an **anticodon**, that can base-pair with its complementary codon in the mRNA.

3. **Ribosomal RNA (rRNA)** associates with a set of proteins to form ribosomes. These complex structures form the scaffold for stepwise alignment of the codons in mRNA with the anticodons in tRNA. The ribosome also catalyzes the sequential formation of peptide bonds between amino acids carried by tRNAs for the assembly of a polypeptide chain. Ribosomes are composed of a large and a small subunit, each of which contains its own rRNA molecule or molecules.

FIGURE 5-29 Three roles of RNA in protein synthesis. Messenger RNA (mRNA) is translated into protein by the joint action of transfer RNA (tRNA) and the ribosome, which is composed of numerous proteins and three (bacterial) or four (eukaryotic) ribosomal RNA (rRNA) molecules (not shown). Note the base pairing between tRNA anticodons and complementary codons in the mRNA. Formation of a peptide bond between the amino-group N on the incoming aa-tRNA and the carboxy-terminal C on the growing protein chain (green) is catalyzed by one of the rRNAs.
$\mathrm{aa} = \mathrm{amino\ acid}; \mathrm{R} = \mathrm{side\ group}$. Note that these are simplified diagrams of tRNAs and the ribosomal subunits. Their actual structures are shown in Figure 5-32b and Figure 5-35.

These three types of RNA participate in the synthesis of proteins in all organisms. In this section, we focus on the decoding of mRNA by tRNAs and how the structure of each of these RNAs relates to its specific task. How they work together with ribosomes and protein factors to synthesize proteins is detailed in the following section. Because translation is essential for protein synthesis, the two processes are commonly referred to interchangeably. However, the polypeptide chains resulting from translation must undergo additional steps after translation, including folding and often other changes (e.g., chemical modifications, association with other chains) that are required for the production of mature, functional proteins (see Chapter 3).

Messenger RNA Carries Information from DNA in a Three-Letter Genetic

Code

As noted previously, the genetic code used by cells is a *triplet* code, in which every three-nucleotide sequence, or codon, is read from a specified starting point in the mRNA. Of the 64 possible codons in the genetic code (one of four nucleotides at each of the three positions of a codon yields $4 \times 4 \times 4 = 64$ possible codons), 61 specify individual amino acids, and 3 are stop codons. Table 5-1 shows that most amino acids are encoded by more than one codon. Only two — methionine and tryptophan — have a single codon; at the other extreme, leucine, serine, and arginine are each specified by six different codons. The different codons that code for a given single amino acid are said to be *synonymous*. The code itself is termed *degenerate*, meaning that a particular amino acid can be specified by several codons.

TABLE 5-1 • The Genetic Code (Codons to Amino Acids)*

First position (5′ end)	Second position: U	C	A	G	Third position (3′ end)
U	Phe	Ser	Tyr	Cys	U
	Phe	Ser	Tyr	Cys	C
	Leu	Ser	Stop	Stop	A
	Leu	Ser	Stop	Trp	G
C	Leu	Pro	His	Arg	U
	Leu	Pro	His	Arg	C
	Leu	Pro	Gln	Arg	A
	Leu (Met)*	Pro	Gln	Arg	G
A	Ile	Thr	Asn	Ser	U
	Ile	Thr	Asn	Ser	C
	Ile	Thr	Lys	Arg	A
	Met (Start)	Thr	Lys	Arg	G
G	Val	Ala	Asp	Gly	U
	Val	Ala	Asp	Gly	C
	Val	Ala	Glu	Gly	A
	Val (Met)*	Ala	Glu	Gly	G

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

*AUG is the most common initiation codon; GUG usually codes for valine; and CUG for leucine, but rarely these codons can also code for methionine to initiate a protein chain.

Synthesis of all polypeptide chains in prokaryotic and eukaryotic cells begins with the amino acid methionine. In bacteria, a specialized form of methionine with a formyl group linked to its amino group is used. In most mRNAs, the *start (initiation) codon* specifying this amino-terminal methionine is AUG. In a few bacterial mRNAs, GUG is used as the initiation codon, and CUG is

occasionally used as an initiation codon for methionine in eukaryotes. The three codons UAA, UGA, and UAG do not specify amino acids, but rather constitute *stop (termination) codons* that mark the carboxyl terminus of polypeptide chains in almost all cells. The sequence of codons that runs from a specific start codon to a stop codon is called a **reading frame**. This precise linear array of ribonucleotides in groups of three in mRNA specifies the precise linear sequence of amino acids in a polypeptide chain and also signals where synthesis of the chain starts and stops.

The great utility of the genetic code table is that it allows the amino acid sequence of the encoded protein to be deduced from the sequence of an mRNA. Since the genetic code is read as a continuous sequence of triplet codons without divisions between them, a particular mRNA theoretically could be translated in three different reading frames (Figure 5-30). Once the sequence of an mRNA is known (usually determined from the DNA sequence of the transcribed gene), it is necessary to determine which of the three possible reading frames is translated by the ribosome into protein sequence. In principle, this could be done by identifying the AUG codon that is the start of translation. In practice, however, finding the correct initiation codon is error prone and the most often used method is to search for a long **open reading frame**. The idea behind this method is that in sequences that do not code for proteins, including the two incorrect reading frames of an mRNA, stop codons should appear randomly as 3 out of 64 codons, and thus

noncoding reading frames should only have relatively short stretches (on average of about 20 amino acid codons) between stop codons. Thus a given mRNA will have two reading frames that are broken up by multiple stop codons and usually only have one long open reading frame not interrupted by stop codons representing the sequence of the encoded protein.

FIGURE 5-30 Three possible reading frames in an mRNA sequence. If translation of the mRNA sequence shown begins at three different upstream start sites (not shown), then three overlapping reading frames are possible. In this example, the codons are shifted one base to the right in the middle frame and two bases to the right in the third frame, which ends in a stop codon. As a result, the same mRNA nucleotide sequence can specify different amino acids. The correct reading frame for a given mRNA sequence can usually be readily identified as the longest open reading frame that is not interrupted by stop codons.

A related use of the genetic code is to deduce the effect that a gene mutation will have on the encoded protein. To see the range of possibilities, imagine the effect of mutations in a serine codon UCG that occurs in the middle of a protein-coding sequence. A mutation changing G $\rightarrow$ A would give a UCA codon, which also encodes serine and is thus a *synonymous mutation*, and would be predicted to have no effect on the function of the encoded protein. By contrast, a mutation changing C $\rightarrow$ U would give a UUG codon, which codes for leucine: this is a *missense mutation* that may have an effect on the function of the protein depending on the importance of serine at that position for protein function. On the other hand, a mutation changing C $\rightarrow$ A would give UAG, which is a stop codon and thus would cause a *nonsense mutation* that would terminate the protein sequence early and would likely cause a complete loss of function. Finally, an addition or subtraction of one or two bases will shift the reading frame. Known as a *frameshift mutation*, such a change in sequence would lead to a scrambled amino sequence with an early termination of the protein. Unless the frameshift mutation occurred near the end of the coding sequence, the likely consequence would be a complete loss of function.

The genetic code shown in Table 5-1 is known as the *universal code* since meaning of each codon is the same in most known organisms — strong evidence that life on Earth evolved only once. The 20 amino acids are not distributed among the 61 sense codons in haphazard fashion, and the underlying structure of the universal

code provides clues to how an optimal code evolved. The most prominent pattern to emerge when the code is considered as a whole is that changing one pyrimidine for another (C $\rightarrow$ U or U $\rightarrow$ C) or changing one purine for another (G $\rightarrow$ A or A $\rightarrow$ G) in either the first or the third position typically either leads to a synonymous codon or changes to a codon for an amino acid with similar chemical properties. These types of sequence changes, as we saw in Section 5.3, are the most frequent kinds of mistakes to be made during DNA replication. Evidently the code evolved to minimize the deleterious effects on the amino acid sequence of proteins of the most common types of mutations in DNA.

The Folded Structure of tRNA Promotes Its Decoding Functions

The two information-carrying polymers, DNA and mRNA, perform their functions with the flexibility to accommodate a vast number of different sequences. On the other hand, tRNAs have specific fixed sequences that allow the tRNA molecules to fold into a three-dimensional structure that is crucial for their function. To participate in protein synthesis, a tRNA molecule must become chemically linked to a particular amino acid via a high-energy bond, forming an **aminoacyl-tRNA** (Figure 5-31). Enzymes called *aminoacyl-tRNA synthetases* are responsible for adding the correct amino acid to a given tRNA and, as will be described, they do this

through the recognition of particular features of the tRNA structure. During the process of translation, an aminoacyl-tRNA interacts with the ribosome and other protein factors so that the anticodon sequence is properly base-paired with a codon in mRNA. All of these interactions also depend on the folded structure of the tRNA (see Figure 5-29).

FIGURE 5-31 Translating nucleic acid sequence into amino acid sequence. (a) The process for translating nucleic acid sequences in mRNA into amino acid sequences in proteins involves two steps. Step **1**: An aminoacyl-tRNA synthetase first couples a specific amino acid, via a high-energy ester bond (yellow), to either the $2'$ or $3'$ hydroxyl of the terminal adenosine in the corresponding tRNA. Step **2**: A three-base sequence in the tRNA (the anticodon) then base-pairs with a codon in the mRNA specifying the attached amino acid. If an error occurs in either step, the wrong amino acid may be incorporated into a polypeptide chain. $\mathrm{Phe} = \mathrm{phenylalanine}$. (Note that this is a simplified diagram of $\mathrm{tRNA}^{\mathrm{Phe}}$; its actual

structure is shown in Figure 5-32b.) (b) Molecular model of the human mitochondrial aminoacyl-tRNA synthetase for Phe in complex with $tRNA^{Phe}$.

[Data from L. Klipcan et al., 2012, *J. Mol. Biol*. **415**:527, PDB ID 3tup.]

Some 30–40 different tRNAs have been identified in bacterial cells and as many as 50–100 in animal and plant cells. Thus the number of tRNAs in most cells is more than the number of amino acids used in protein synthesis (20), but less than the number of amino acid codons in the genetic code (61). Consequently, many amino acids have more than one tRNA to which they can attach (explaining how there can be more tRNAs than amino acids); in addition, many tRNAs can pair with more than one codon (explaining how there can be more codons than tRNAs).

tRNA molecules, which are 70–80 nucleotides long, are initially formed by transcription from a tRNA gene template. The maturation of the primary transcript to a functional tRNA molecule with precise three-dimensional structure takes place in three stages. The first stage is the chemical modification of certain bases, creating nonstandard nucleotides, such as inosine, dihydrouridine, and pseudouridine. As we will see shortly, some of these modified bases are known to play an important role in protein synthesis. The second stage involves complementary base pairing between antiparallel arrangements of segments of the same tRNA molecule to produce a form that resembles a cloverleaf when drawn in two dimensions (Figure 5-32a). The four short, double-helical segments

that form are stabilized mostly by Watson-Crick base pairing, although other nonstandard base pairs, such as G·U, are accommodated by the helical structures that are much less uniform than that of DNA. Three of the four helical stems have loops containing seven or eight bases at their ends, while the remaining, unlooped stem contains the free 3′ and 5′ ends of the chain. The three nucleotides composing the anticodon are located at the center of the middle loop, in an accessible position that facilitates codon-anticodon base pairing. In all tRNAs, the 3′ end of the unlooped *acceptor stem*, to which a specific amino acid is attached, has the sequence CCA, which in most cases is added after synthesis and processing of the tRNA are complete. Finally, the first and third loops join together by base pairing to form a compact, L-shaped structure when viewed in three dimensions. The anticodon loop and acceptor stem form the ends of the folded tRNA molecule (Figure 5-32b).

FIGURE 5-32 Structure of tRNAs. (a) Although the exact nucleotide sequence varies among tRNAs, they all fold into four base-paired stems and three loops. The CCA sequence at the $3'$ end is also found in all tRNAs. Attachment of an amino acid to the $3'$ A yields an aminoacyl-tRNA. Some of the A, C, G, and U residues are modified post-transcriptionally in most tRNAs (see key). Dihydrouridine (D) is nearly always present in the D loop; likewise, ribothymidine (T) and pseudouridine (ψ) are almost always present in the TψCG loop. Yeast alanine tRNA, represented here, also contains other modified bases. The triplet at the tip of the anticodon loop base-pairs with the corresponding codon in mRNA. See R. W. Holly et al., 1965, *Science* **147**:1462. (b) Three-dimensional model of the generalized backbone of all tRNAs. Note the L shape of the molecule.

[Part (b) Data from J. G. Arnez and D. Moras, 1997, *Trends Biochem. Sci.* **22**:211, PDB ID 1vtq.]

Nonstandard Base Pairing Often Occurs Between Codons and Anticodons

If perfect Watson-Crick base pairing between codons and anticodons were required, cells would have to contain at least 61 different types of tRNAs, one for each codon that specifies an amino acid. As noted previously, however, many cells contain fewer than 61 tRNAs. The explanation for the smaller number lies in the capability of a single tRNA anticodon to recognize more than one, but not necessarily every, codon corresponding to a given amino acid. This broader recognition can occur because of nonstandard pairing between bases in the so-called *wobble* position: that is, the third ($3'$) base in an mRNA codon and the corresponding first ($5'$) base in its tRNA anticodon.

The first and second bases of a codon almost always form standard Watson-Crick base pairs with the third and second bases, respectively, of the corresponding anticodon, but four nonstandard interactions can occur between bases in the wobble position. Particularly important is the G·U base pair, which fits into the short, 3-bp RNA-RNA double-stranded region formed between the codon and the anticodon almost as well as the standard G·C pair. Thus a tRNA anticodon with G in the first (wobble) position can base-pair with the two corresponding codons that have either pyrimidine (C or U) in the third position (see Figure 5-26). For example, the phenylalanine codons UUU and UUC ($5' \rightarrow 3'$) are both recognized by the tRNA that has GAA ($5' \rightarrow 3'$) as its anticodon. In fact, any two codons of the type NNPyr ($\mathrm{N} = \text{any base}; \mathrm{Pyr} = \text{pyrimidine}$) encode a single amino acid and are decoded by a single tRNA with G in the first (wobble) position of the anticodon.

Although adenine is rarely found in the anticodon wobble position, many tRNAs in plants and animals contain inosine (I), a deaminated product of adenine, at this position. Inosine can form nonstandard base pairs with A, C, and U. A tRNA with inosine in the wobble position thus can recognize the corresponding mRNA codons with A, C, or U in the third (wobble) position (see Figure 5-33). For this reason, inosine-containing tRNAs are heavily employed in translation of the synonymous codons that specify a single amino acid. For example, four of the six codons for leucine (CUA, CUC, CUU, and UUA) are all recognized by the same tRNA with the

anticodon 3′-GAI-5′; the inosine in the wobble position forms nonstandard base pairs with the third base in each of these four codons.

FIGURE 5-33 Nonstandard base pairing at the wobble position. The base in the third (or wobble) position of an mRNA codon often forms a nonstandard base pair with the base in the first (or wobble) position of a tRNA anticodon. Wobble pairing allows a tRNA to recognize more than one mRNA codon, although each of those tRNAs will bear the same amino acid. Note that a tRNA with I (inosine) in the wobble position can read (become paired with) three different codons, and a tRNA with G or U in the wobble position can read two codons. Although A is theoretically possible in the wobble position of the anticodon, it is almost never found in nature. (Note that this is a simplified diagram of a tRNA. The actual structure of a tRNA is shown in Figure 5-32b.)

Amino Acids Are Linked to Their Cognate tRNAs with Great Accuracy

Recognition of the codon or codons specifying a given amino acid by a particular tRNA is actually the second step in decoding the genetic message. The first step, attachment of the appropriate amino acid to a tRNA, is catalyzed by a specific aminoacyl-tRNA synthetase. Each of the 20 different synthetases recognizes *one* amino acid and *all* its compatible, or *cognate*, tRNAs. These coupling enzymes link an amino acid to the free 2′ or 3′ hydroxyl of the adenosine at the 3′ terminus of the tRNA molecule by an ATP-requiring reaction. In this reaction, the amino acid is linked to the tRNA by a high-energy bond and is thus said to be *activated.* The energy of this bond subsequently drives the formation of the peptide bonds linking adjacent amino acids in a growing polypeptide chain. The equilibrium of the aminoacylation reaction is driven further toward activation of the amino acid by hydrolysis of the high-energy phosphoanhydride bond in the released pyrophosphate (see Figure 5-31a).

Each aminoacyl-tRNA synthetase must specifically recognize two substrates; the amino acid and the corresponding set of cognate tRNAs. Any errors made in tRNA charging could lead to a deleterious error in translation and the aminoacyl-tRNA synthetases have evolved to have high fidelity, mischarging a tRNA only about one in 10^4 times. As one would expect, most aminoacyl-tRNA synthetases recognize their cognate tRNAs by interacting with the anticodon loop. However, for amino acids that have multiple codons, other features common to all the cognate tRNAs contribute to specific

recognition. In an extreme case, in *E. coli*, the four tRNAs for alanine are not recognized by their anticodon loop at all. Instead, all four tRNAs contain a unique G·U base pair in the acceptor stem, which is used for specific recognition by the corresponding aminoacyl tRNA synthetase. In other instances, specific bases in incorrect tRNAs that are structurally similar to a cognate tRNA will inhibit charging of the incorrect tRNA. Thus recognition of the correct tRNA depends on both positive interactions and the absence of negative interactions.

A second source of errors in charging of tRNAs by aminoacyl-tRNA synthetases is selection of the wrong amino acid. In cases in which mischarging by a structurally very similar amino acid is possible, the aminoacyl-tRNA synthetase has evolved a second active site with a *proofreading* activity. For example, a single active site in the aminoacyl-tRNA synthetase for isoleucine would not be able to effectively exclude valine, which is similar to isoleucine but lacks one methyl group. For this enzyme, there is a second proofreading site that can remove an incorrect amino acid that has been added to $tRNA^{Ile}$. The hydrophobic pocket for this site is too small to admit isoleucine, but it can admit valine that has been erroneously linked to $tRNA^{Ile}$ and will remove it. This mechanism of proofreading by aminoacyl-tRNA synthetases is similar in outline to proofreading of incorrect nucleotide incorporation by the $3' \rightarrow 5'$ exonuclease activity of DNA polymerase.

KEY CONCEPTS OF SECTION 5.5

The Decoding of mRNA by tRNAs

- Genetic information from DNA is carried by mRNA in the form of a non-overlapping, degenerate triplet code.
- Each amino acid is encoded by one or more three-nucleotide sequences (codons) in mRNA. Each codon specifies one amino acid, but most amino acids are encoded by multiple codons (see Table 5-1).
- The AUG codon for methionine is the most common start codon, specifying the amino acid at the amino-terminus of a protein chain. Three codons (UAA, UAG, UGA) function as stop codons and specify no amino acids.
- There are three possible reading frames for the translation of a given mRNA sequence. The protein coding sequence can be identified as a long open reading frame that is not interrupted by stop codons.
- The genetic code can be used to determine the linear sequence of amino acids in a protein sequence and to deduce the effect of gene mutations on the encoded protein.
- All tRNAs have a similar three-dimensional structure that includes an acceptor stem for attachment of a specific amino acid and a stem-loop with a three-base anticodon sequence at its end (see Figure 5-32). The anticodon can base-pair with its corresponding codon in mRNA.
- Because of nonstandard interactions, a tRNA may base-pair with more than one mRNA codon; conversely, a particular codon may base-pair with multiple tRNAs. In each case, however, only the proper amino acid is inserted into a growing polypeptide chain.
- Each of the 20 aminoacyl-tRNA synthetases recognizes a single amino acid and covalently links it to a cognate tRNA, forming an aminoacyl-tRNA (see Figure 5-31). This reaction activates the amino acid so that it can participate in peptide bond formation.

5.6 Stepwise Synthesis of Proteins on Ribosomes

The previous sections have introduced two of the major participants in protein synthesis: mRNAs and aminoacyl-tRNAs. Here we first describe the third key player in protein synthesis — the rRNA-containing ribosome — before taking a detailed look at how all three components are brought together to carry out the biochemical events leading to the formation of polypeptide chains by ribosomes. The complex process of translation can be divided into three stages — initiation, elongation, and termination — which we consider in order. We focus our description on translation in eukaryotic cells, but the mechanism of translation is fundamentally the same in all cells.

Ribosomes Are Protein-Synthesizing Machines

In simple terms, the ribosome serves both as a scaffold to facilitate the binding aminoacyl-tRNAs to sequential codons in the mRNA and as an enzyme to catalyze the peptidyl transfer reaction for the stepwise formation of peptide bonds in the growing polypeptide chain. The ribosome is responsible for all protein synthesis and is the most abundant RNA-protein complex in the cell. Elongation of polypeptides occurs at a rate of 3 to 5 amino acids added per second,

so that although small proteins may be made in a minute or less, the formation of very large proteins such as titin, a muscle protein of about 30,000 amino acid residues, takes 2–3 hours. The ribosome must therefore be precise, and it must be persistent.

With the aid of the electron microscope, ribosomes were first discovered as small, discrete, RNA-rich particles found to be most abundant in those cells most active in protein synthesis. However, their direct role in protein synthesis was not recognized until reasonably pure ribosome preparations were obtained. In vitro radiolabeling experiments with such preparations showed that radioactive amino acids were first incorporated into growing polypeptide chains associated with ribosomes before appearing in finished proteins.

Although there are differences between the ribosomes of bacteria, archaea, and eukaryotes, the great structural and functional similarities between ribosomes from all species reflect the common evolutionary origin of the most basic constituents of living cells. A ribosome is composed of three (in bacteria and archaea) or four (in eukaryotes) distinct rRNA molecules and as many as 80 proteins, organized into a large subunit and a small subunit (Figure 5-34 and Table 5-2). The ribosomal subunits and the rRNA molecules are commonly designated in Svedberg units (S), a measure of the sedimentation rate of macromolecules centrifuged under standard conditions — essentially, a logarithmic measure of size. The small ribosomal subunit contains a single rRNA molecule, referred to as

small rRNA. The large subunit contains a molecule of *large rRNA* and one molecule of 5S rRNA, plus an additional molecule of 5.8S rRNA in eukaryotes. The lengths of the rRNA molecules, the numbers of proteins in each subunit, and consequently, the sizes of the subunits differ between bacterial and eukaryotic cells (see Table 5-2). The assembled ribosome is 70S in bacteria and 80S in vertebrates.

FIGURE 5-34 Structure of the bacterial ribosome. Model of the *Thermus thermophilus* ribosome viewed along the interface between the large (50S) and small (30S) subunits. The 16S rRNA and proteins in the small subunit are dark gray. RNA is depicted as a tube model and protein surfaces are shown. The 23S rRNA and proteins in the large subunit are light gray, and the 5S rRNA is an intermediate shade

of gray. The surface of the ribosome is made partially transparent to display the positions of bound tRNAs. Note that the ribosomal proteins are located primarily on the surface of the ribosome.

The sequences of the small and large rRNAs from thousands of organisms are now known. Although the primary nucleotide sequences of these rRNAs vary considerably, the same parts of each type of rRNA contain complementary sequences that can form internally base-paired segments, indicating that they all share the same core structure. Since every organism has ribosomes, differences between their rRNA sequences have proven to be the most reliable means to determine the evolutionary distances between organisms. Even today, when whole genome sequences are

often available, phylogenetic comparisons usually begin with the sequence of the respective rRNA genes.

The three-dimensional structures of bacterial and yeast ribosomes (see Figure 5-35) and of the large subunit of an archaeal ribosome have been determined by x-ray crystallography. The structures of human (see Figure 5-35d) and plant ribosomes have also been determined by cryoelectron microscopy. The structure of the rRNAs in the common core, where mRNAs and tRNAs are bound and where peptide bond formation is catalyzed, is similar in all three domains of life. However, archaeal rRNAs and proteins are more similar to those of eukaryotic ribosomes than to those of bacterial ribosomes, reflecting their later divergence from a common ancestor (see Figure 1-1). For the most part, the multiple ribosomal proteins are much smaller than the rRNAs and associate with the surface of the ribosomes. Although the number of protein molecules in ribosomes greatly exceeds the number of RNA molecules, RNA constitutes about 60 percent of the mass of a bacterial ribosome and about 50 percent of the mass of a human ribosome. Eukaryotic ribosomes are generally similar to bacterial ribosomes but are larger because of eukaryote-specific insertions of RNA segments into regions of the common core rRNAs as well as the presence of a larger number of proteins (see Figure 5-35 and Table 5-2). Basic aspects of protein synthesis are thought to be similar among all three domains of life, although initiation of translation in eukaryotes, discussed later, is more complex and subject to additional mechanisms of regulation.

FIGURE 5-35 Comparison of the common core structure at the center of ribosomes from all domains of life and bacterial, yeast, and human ribosomes. (a) RNA in the common core structure is shown in light blue and protein domains common to all ribosomes are shown in pink. Additions to the common core structure are shown in dark blue for RNA and red for proteins in ribosomes from *T. thermophilus* (b) and *S. cerevisiae* (c). (d) Human ribosome structure from cryoelectron microscopy. A tRNA visible in the E site is shown in green.

The most therapeutically effective antibiotics target processes in bacterial cells that are essential for life and are fundamentally different between bacterial and mammalian cells. Because ribosomes satisfy both criteria, the bacterial ribosome has been a major target for the development of new antibiotics. The high-resolution structures of ribosomes are providing new insights into the mechanism by which many antibiotics inhibit bacterial protein synthesis without affecting the function of mammalian ribosomes. These insights are providing important clues for the design and synthesis of new antibiotics. Such research is desperately needed as the occurrence of bacteria resistant to currently available antibiotics

becomes increasingly more common, especially in hospitals, where antibiotic-resistant bacteria are under positive selection. ■

Methionyl-$tRNA_i^{Met}$ Recognizes the AUG Start Codon

As noted earlier, the AUG codon for methionine functions as the start codon in the vast majority of mRNAs. A critical aspect of translation initiation is to begin protein synthesis at the start codon, thereby establishing the correct reading frame for the entire mRNA. Both bacteria and eukaryotes contain two different methionine tRNAs: $tRNA_i^{Met}$ can initiate protein synthesis, and $tRNA^{Met}$ can incorporate methionine only into a growing protein chain. The same aminoacyl-tRNA synthetase (MetRS) charges both tRNAs with methionine, but *only* Met-$tRNA_i^{Met}$ (i.e., activated methionine attached to $tRNA_i^{Met}$) can bind at the appropriate site on the small ribosomal subunit, the *P site*, to begin synthesis of a polypeptide chain. The regular Met-$tRNA^{Met}$, and all other charged tRNAs, bind only to the *A site*, as described later. tRNAs enter the exit or *E site* after transferring their covalently bound amino acids to the growing polypeptide chain.

Eukaryotic Translation Initiation Usually Occurs at the First AUG

Downstream from the 5′ End of an mRNA

During the first stage of translation, the small and large ribosomal subunits assemble around an mRNA that has a Met-$tRNA_i^{Met}$ correctly positioned at the start codon in the ribosomal P site. In eukaryotes, the assembly of this complex is mediated by a special set of proteins known as **eukaryotic translation initiation factors (eIFs)**. As each individual component joins the complex, it is guided by interactions with specific eIFs. Several of the initiation factors bind GTP, and the hydrolysis of GTP to GDP functions as a switch to ensure that the assembly pathway proceeds in an orderly and irreversible fashion. By coupling of assembly to the essentially irreversible step of GTP hydrolysis ensures that, once formed, the appropriate complexes are stable.

The current model for initiation of translation in vertebrates is depicted in Figure 5-36. Large and small ribosomal subunits released from a previous round of translation are kept apart by the binding of eIFs 1, 1A, and 3 to the small 40S subunit (Figure 5-36, *top*). The first step of translation initiation is formation of a *43S preinitiation complex*. This preinitiation complex is formed when the 40S subunit with eIFs 1, 1A, and 3 associates with eIF5 and a ternary (three-part) complex consisting of the Met-$tRNA_i^{Met}$ and eIF2 bound to GTP (Figure 5-36, steps **1** and **2**). The initiation factor eIF2 alternates between association with GTP and GDP; it can bind

Met-$tRNA_i^{Met}$ only when it is associated with GTP. Cells can inhibit protein synthesis by phosphorylating a serine residue on the eIF2 bound to GDP; the phosphorylated complex is unable to exchange the bound GDP for GTP and cannot bind Met-$tRNA_i^{Met}$, so protein synthesis cannot occur.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 5-36 Initiation of translation in eukaryotes. The current model of eukaryotic initiation involves eight steps. Step **1**: An eIF2 ternary complex forms when eIF2 · GTP binds a $\mathrm{tRNA}_{\mathrm{i}}^{\mathrm{Met}}$. Step **2**: When a ribosome dissociates at the termination of translation, the 40S subunit is bound by eIF1, eIF1A, and eIF3. A 43S preinitiation complex forms when this subunit associates with an eIF2 ternary complex and eIF5. Step **3**: An mRNA is activated when a multisubunit eIF4 complex binds: subunit eIF4E binds to the $5'$ cap, and subunit eIF4G binds multiple copies of the cytoplasmic poly(A)-binding protein (PABPC) bound to the mRNA poly(A) tail. For simplicity, binding of only one PABPC to eIF4G is shown. Then eIF4B, which stimulates eIF4A helicase activity, also joins this circular complex in which both the mRNA $5'$ cap and poly(A) tail are associated with the eIF4 complex. Step **4**: The 43S preinitiation complex binds an eIF4-mRNA complex. Step **5**: The RNA helicase activity of subunit eIF4A unwinds any RNA secondary structure at the $5'$ end of the mRNA as the 40S subunit scans in the $5' \rightarrow 3'$ direction until it recognizes the initiation codon. For simplicity, eIF4E is diagrammed as releasing from the remainder of the eIF4 complex, but in reality, it remains associated, forming a loop in the mRNA between the $5'$ cap and the scanning eIF4 complex. Step **6**: Recognition of the initiation codon causes eIF5 to stimulate hydrolysis of eIF2-bound GTP. This switches the conformation of the scanning complex to a 48S initiation complex with the anticodon of $\mathrm{tRNA}_{\mathrm{i}}^{\mathrm{Met}}$ base-paired to the initiator AUG in the 40S-subunit P site. Step **7**: The 60S subunit joins the 40S subunit, leading to the release of most of the earlier-acting eIFs as eIF5B-GTP binds to eIF1A in the ribosomal A site. The released eIF4 complex and eIF4B associate with the $5'$ cap and PABPC as shown in step **3** to prepare for interaction with another 43S preinitiation complex. For simplicity, this association is not shown. Step **8**: Correct association of the 40S and 60S subunits results in hydrolysis of eIF5B-bound GTP, release of eIF5B-GDP and eIF1A, and formation of the 80S initiation complex with $\mathrm{tRNA}_{\mathrm{i}}^{\mathrm{Met}}$ base-paired to the initiation codon in the ribosomal P site. See R. J. Jackson et al., 2010, *Nat. Rev. Mol. Cell Biol.* **11**:113.

The mRNA to be translated is bound by the multisubunit eIF4 complex, which interacts with both the $5'$ cap and the cytoplasmic poly(A)-binding protein (PABPC) bound in multiple copies to the mRNA poly(A) tail. Both interactions are required for translation of most mRNAs. This binding results in the formation of a circular

complex (Figure 5-36, step **3**). The eIF4 cap-binding complex consists of several subunits with different functions. The eIF4E subunit binds the 5′ cap on mRNAs (see Figure 5-13). The large eIF4G subunit binds cooperatively to several PABPC proteins bound to the mRNA poly(A) tail and also forms a scaffold to which the other eIF4 subunits bind. The mRNA-eIF4 complex then associates with the preinitiation complex through an interaction between eIF4G and eIF3 (step **4**).

The initiation complex slides along, or *scans*, the associated mRNA, with eIF4A, stimulated by eIF4B, unwinding the RNA secondary structure by using energy from ATP hydrolysis (step **5**). Scanning stops when the $tRNA_i^{Met}$ anticodon recognizes the start codon, which is the first AUG downstream from the 5′ end in most eukaryotic mRNAs. Recognition of the start codon leads to hydrolysis of the GTP associated with eIF2, an irreversible step that prevents further scanning, resulting in formation of the *48S initiation complex* (step **6**). This commitment to the correct initiation codon is facilitated by eIF5, an eIF2 GTPase–activating protein (GAP, see Figure 3-35). Selection of the initiating AUG is facilitated by specific surrounding nucleotides called the *Kozak sequence*, for Marilyn Kozak, who defined it: (5′)ACC**AUGG**(3′). The A preceding the AUG (in bold) and the G immediately following it are the most important nucleotides affecting translation initiation efficiency.

Association of the large (60S) subunit with the small subunit, which is mediated by eIF5B bound to GTP, results in displacement of many of the initiation factors (step **7**). Correct association between the ribosomal subunits results in hydrolysis of the eIF5B-bound GTP to GDP and the release of eIF5B-GDP and eIF1A (step **8**), completing the formation of an *80S initiation complex*. Coupling of the ribosome subunit–joining reaction to GTP hydrolysis by eIF5B allows the initiation process to continue only when the subunit interaction has occurred correctly. It also makes this an irreversible step, so that the ribosomal subunits do not dissociate until the entire mRNA is translated and protein synthesis is terminated.

The eukaryotic protein-synthesizing machinery begins translation of most cellular mRNAs within about 100 nucleotides of the 5′-capped end, as just described. However, some cellular mRNAs contain an internal ribosome entry site (IRES) located far downstream from the 5′ end. It is thought that cellular IRESs form RNA structures that interact with a complex of eIF4A and eIF4G, which then associates with eIF3 bound to a 40S subunit with eIF1 and eIF1A. This assembly then binds an eIF2 ternary complex to assemble an initiation complex directly on a neighboring AUG codon. In addition, translation of some viral RNAs, which lack a 5′ cap, is initiated at viral IRES sequences. These RNAs fall into different classes depending on how many of the standard eIFs are required for initiation. In the case of cricket paralysis virus, the ~200-nt-long IRES folds into a complex structure that interacts

directly with the 40S ribosomal subunit and leads to initiation without any of the eIFs or even the initiator Met-$tRNA_i^{Met}$.

During Chain Elongation Each Incoming Aminoacyl-tRNA Moves Through Three Ribosomal Sites

The correctly positioned ribosome–Met-$tRNA_i^{Met}$ complex is now ready to begin the task of stepwise addition of amino acids by in-frame translation of the mRNA. As is the case with initiation, a set of specialized proteins, termed translation **elongation factors (EFs)**, is required to carry out this process of chain elongation. The key steps in elongation are the entry of each succeeding aminoacyl-tRNA with an anticodon complementary to the next codon, the formation of a peptide bond, and the movement, or *translocation*, of the ribosome one codon at a time along the mRNA.

At the completion of translation initiation, as noted already, Met-$tRNA_i^{Met}$ is bound to the P site on the assembled 80S ribosome (Figure 5-37, *top*). This region of the ribosome is called the *P* site because the tRNA chemically linked to the growing poly*p*eptide chain is located here. The second aminoacyl-tRNA is brought into the ribosome as a ternary complex in association with EF1α·GTP and becomes bound to the *A* site, so named because it is where *a*minoacyl-tRNAs bind (step **1**). EF1α·GTP bound to various

aminoacyl-tRNAs diffuse into the A site, but the next step in translation proceeds only when the tRNA anticodon base-pairs with the second codon in the coding region. When that occurs properly, the GTP in the associated EF1α·GTP is hydrolyzed. The hydrolysis of GTP promotes a conformational change in EF1α that leads to release of the resulting EF1α·GDP complex and tight binding of the aminoacyl-tRNA in the A site (step **2**). This conformational change also positions the aminoacylated 3′ end of the tRNA in the A site close to the 3′ end of the Met-$tRNA_i^{Met}$ in the P site. GTP hydrolysis, and hence tight binding, does not occur if the anticodon of the incoming aminoacyl-tRNA cannot base-pair with the codon at the A site. In this case, the ternary complex diffuses away, leaving an empty A site that can associate with other aminoacyl-tRNA–EF1α·GTP complexes until a correctly base-paired tRNA is bound. Thus GTP hydrolysis by EF1α is another proofreading step that allows protein synthesis to proceed only when the correct aminoacyl-tRNA is bound to the A site. This phenomenon contributes to the fidelity of protein synthesis.

Lodish et a

FIGURE 5-37 Chain elongation in eukaryotes. Once the 80S ribosome with Met-$\mathrm{tRNA_i^{Met}}$ in the ribosome P site is assembled (*top*), a ternary complex bearing the second amino acid ($\mathrm{aa_2}$) coded by the mRNA binds to the A site (step **1**). Following a conformational change in the ribosome induced by hydrolysis of GTP in EF1α·GTP (step **2**), the large rRNA catalyzes peptide bond formation between $\mathrm{Met_i}$ and $\mathrm{aa_2}$ (step **3**). Hydrolysis of GTP in EF2·GTP causes another conformational change in the ribosome that results in its translocation one codon along the mRNA and shifts the unacylated $\mathrm{tRNA_i^{Met}}$ to the E site and the tRNA with the bound peptide to the P site (step **4**). The cycle can begin again with binding of a ternary complex bearing

aa_3 to the now open A site. In the second and subsequent elongation cycles, the tRNA at the E site is ejected during step **2** as a result of the conformational change induced by hydrolysis of GTP in EF1α·GTP.

With the initiating Met-$tRNA_i^{Met}$ at the P site and the second aminoacyl-tRNA tightly bound at the A site, the α-amino group of the second amino acid reacts with the *activated* (ester-linked) methionine on the initiator tRNA, forming a peptide bond (Figure 5-37, step **3**; see Figure 5-29). Since the vast majority of cellular catalysts are protein enzymes, it was long assumed that the catalyst for peptide transfer would be one of the ribosomal proteins. It therefore came as quite a surprise when the high-resolution crystal structure of the bacterial large ribosomal subunit revealed that no proteins lie near the site of peptide bond synthesis and that the peptidyltransferase reaction was likely catalyzed by the large rRNA. The catalytic ability of the large rRNA in bacteria has been demonstrated by carefully removing the vast majority of the protein from large ribosomal subunits. The nearly pure bacterial 23S rRNA can catalyze a peptidyltransferase reaction between analogs of aminoacyl-tRNA and peptidyl-tRNA. The 2′-hydroxyl of the terminal A of the peptidyl-tRNA in the P site also participates in catalysis.

Following peptide bond synthesis, the ribosome translocates a distance equal to one codon along the mRNA. This translocation step is monitored by hydrolysis of the GTP in eukaryotic EF2·GTP. Once translocation has occurred correctly, the bound GTP is hydrolyzed, another irreversible process that prevents the ribosome

from moving along the RNA in the wrong direction or from translocating an incorrect number of nucleotides. As a result of conformational changes in the ribosome that accompany proper translocation and the resulting GTP hydrolysis by EF2, $tRNA_i^{Met}$, now without its activated methionine, is moved to the *E (e*xit) site on the ribosome; concurrently, the second tRNA, now covalently bound to a dipeptide (a peptidyl-tRNA), is moved to the P site (Figure 5-37, step **4**). Translocation thus returns the ribosome conformation to a state in which the A site is open and able to accept another aminoacyl-tRNA complexed with EF1α·GTP, beginning another cycle of chain elongation.

Repetition of the elongation cycle depicted in Figure 5-37 adds amino acids one at a time to the carboxyl terminus of the growing polypeptide, as directed by the mRNA sequence, until a stop codon is encountered. In subsequent cycles, the conformational change that occurs in step **2** ejects the unacylated tRNA from the E site. As the nascent polypeptide chain becomes longer, it threads through a channel in the large ribosomal subunit, exiting at a position opposite the side that interacts with the small subunit (Figures 5-34).

In the absence of the ribosome, the three-base-pair RNA-RNA hybrid between the tRNA anticodons and the mRNA codons in the A and P sites would not be stable; RNA-RNA duplexes between separate RNA molecules must be considerably longer to be stable under physiological conditions. However, multiple interactions between

the large and small rRNAs and the general domains of tRNAs (e.g., the D and TψCG loops, see Figure 5-32) stabilize the tRNAs in the A and P sites, while other RNA-RNA interactions sense correct codon-anticodon base pairing, ensuring that the genetic code is read properly. Then, interactions between rRNAs and the general domains of all tRNAs result in the movement of the tRNAs between the A, P, and E sites as the ribosome translocates along the mRNA one three-nucleotide codon at a time.

Translation Is Terminated by Release Factors When a Stop Codon Is Reached

The final stages of translation, like initiation and elongation, require highly specific molecular signals that decide the fate of the mRNA–ribosome–peptidyl-tRNA complex. Two types of eukaryotic protein **release factors (RFs)** have been discovered. The first, eRF1, whose shape is similar to that of tRNAs, acts by binding to the ribosomal A site and recognizing stop codons directly. Like some of the initiation and elongation factors discussed previously, the second release factor, eRF3, is a GTP-binding protein. The eRF3·GTP complex acts in concert with eRF1 to promote cleavage of the peptidyl-tRNA bond, thus releasing the completed protein chain and terminating translation (Figure 5-38). The peptidyl-tRNA bond of the tRNA in the P site is not cleaved until one of the three stop codons is correctly

recognized by eRF1, another example of a proofreading step in protein synthesis.

FIGURE 5-38 Termination of translation in eukaryotes. When a ribosome bearing a nascent protein chain reaches a stop codon (UAA, UGA, UAG), release factor eRF1 enters the A site together with eRF3·GTP. Hydrolysis of the bound GTP is accompanied by cleavage of the peptide chain from the tRNA in the P site and ejection of the tRNA in the E site, forming a post-termination complex. The ribosomal subunits are separated by the action of the ABCE1 ATPase together with eIF1, eIF1A, and eIF3. The 40S subunit is released bound to these eIFs, ready to initiate another cycle of translation (see Figure 5-36).

Release of the completed protein leaves a free tRNA in the P site and the mRNA still associated with the 80S ribosome, to which eRF1 and eRF3·GDP are still bound in the A site. In eukaryotes, ribosome recycling occurs when this post-termination complex is bound by a protein called *ABCE1*, which uses energy from ATP hydrolysis to separate the subunits and release the mRNA and tRNA in the P site. Initiation factors eIF1, eIF1A, and eIF3, which are also required for separation of the subunits, load onto the 40S subunit, making it ready for another round of initiation (see Figure 5-36, *top*). In reality, a free mRNA is never released, as diagrammed in Figure 5-25 for simplicity. Rather, the mRNA has other ribosomes associated with it in various stages of elongation, PABPC bound to the poly(A) tail, and the eIF4 complex associated with the 5′ cap, ready to associate with another 43S preinitiation complex (see Figure 5-36).

In addition to these functions in protein synthesis, ribosomes also associate transiently with protein chaperones that assist in folding the polypeptide chain as it emerges from the ribosome surface (see Figure 3-19). As we will see in Chapter 13, ribosomes that synthesize proteins destined to be inserted into the endoplasmic reticulum (ER) associate with a ribonucleoprotein complex called *SRP* (signal recognition particle) that arrests protein synthesis until the nascent polypeptide encounters specialized channels for insertion into the ER. SRP also assists with the insertion and threading of these proteins through these ER channels when protein synthesis is permitted to resume.

Polysomes and Rapid Ribosome Recycling Increase the Efficiency of Translation

Translation of a single eukaryotic mRNA molecule to yield a typically sized protein takes 1 to 2 minutes. Two phenomena significantly increase the overall rate at which cells can synthesize a protein: the simultaneous translation of a single mRNA molecule by multiple ribosomes, and rapid recycling of ribosomal subunits after they disengage from a stop codon. Simultaneous translation of an mRNA by multiple ribosomes is readily observable in electron micrographs and by sedimentation analysis, revealing mRNA molecules attached to multiple ribosomes bearing nascent growing

polypeptide chains. These structures, referred to as **polyribosomes** or *polysomes*, were seen to be circular in electron micrographs of some tissues.

Subsequent studies with purified initiation factors explained the circular shape of polyribosomes and suggested the mechanism by which ribosomes recycle efficiently. These studies revealed that multiple copies of the cytoplasmic poly(A)-binding protein (PABPC) interact with both an mRNA poly(A) tail and the eIF4G subunit of eIF4. Since the eIF4E subunit of eIF4 binds to the cap structure on the 5′ end of an mRNA, the two ends of an mRNA molecule are bridged by the intervening proteins, forming circular mRNA (Figure 5-39a). Because the two ends of a polysome are relatively close together, ribosomal subunits that disengage from a stop codon are positioned near the 5′ end, facilitating reinitiation by the interaction of the 40S subunit and its associated initiation factors with eIF4 bound to the 5′ cap. The circular pathway depicted in Figure 5-39b is thought to enhance ribosome recycling and thus increase the efficiency of protein synthesis.

EXPERIMENTAL FIGURE 5-39 Circular structure of mRNA increases translation efficiency. Eukaryotic mRNA forms a circular structure owing to interactions of three proteins. (a) In the presence of purified yeast poly(A)-binding protein [PABP; there is only one PABP in *S. cerevisiae*, rather than a nuclear (PABPN) and cytoplasmic (PABPC) protein as in higher eukaryotes], eIF4E, and eIF4G, eukaryotic mRNAs form circular structures, visible in this force-field electron micrograph. In these structures, protein-protein and protein-mRNA interactions form a bridge between the $5'$ and $3'$ ends of the mRNA. (b) Model of protein synthesis on circular polysomes and recycling of ribosomal subunits. Multiple individual ribosomes can simultaneously translate a eukaryotic mRNA, shown here in a circular form stabilized by interactions between proteins bound at the $3'$ and $5'$ ends. When a ribosome completes translation and dissociates from the $3'$ end, the separated subunits can rapidly find the nearby $5'$ cap $(\mathrm{m}^7\mathrm{G})$ and PABPC-bound poly(A) tail and initiate another round of synthesis.

GTPase-Superfamily Proteins Function in Several Quality-Control Steps of Translation

We have now seen that one or more GTP-binding proteins participate in each stage of translation. These proteins belong to the **GTPase superfamily** of switch proteins that cycle between a GTP-bound form and a GDP-bound form (see Figure 3-35). Usually correct execution of some preceding assembly step is required to trigger hydrolysis of the bound GTP. The hydrolysis of bound GTP to bound GDP is essentially irreversible and causes a conformational change in the GTPase itself, thus ensuring that the next interdependent assembly step associated with translation proceeds rapidly, unidirectionally, and with high fidelity. As the details of translation have been worked out, two distinct but not mutually exclusive functions of GTP hydrolysis have been identified. The first is to make an assembly event unidirectional by locking associated proteins into place once components have come together in the correct manner. A good example of this is successful association of the large and small ribosomal subunits coupled to hydrolysis of GTP by eIF5B (Figure 5-36, step **8**). Recall that if the correct complex does not form, eIF5B·GTP does not hydrolyze the GTP and the complex is unstable, free to diffuse apart and try again. When the precise alignment of the subunits required for elongation occurs, eIF5B hydrolyzes the GTP to GDP, locking the correct complex in place. Energy released from the high energy β-γ bond in GTP drives the reaction in one direction. A second function of GTP hydrolysis is to create an additional step by which the correct fit for a molecular association can be checked to increase the fidelity of translation. The best example of such a proofreading activity occurs during the crucial process of matching the correct aminoacyl-tRNA with the

next available codon in an mRNA. An initial match is made when the anticodon of an aminoacyl-tRNA in complex with EF1α·GTP docks with the codon in the A site. Then as a distinct step, hydrolysis of EF1α·GTP to EF1α·GDP occurs only after correct base pairing between anticodon and codon is confirmed. GTP hydrolysis causes a conformational change in EF1α that results in the release of its bound tRNA, allowing the aminoacylated 3′ end of the charged tRNA to move into the position required for peptide bond formation (see Figure 5-37, step **2**). In effect, the base pairing between anticodon and codon is checked twice; first in the initial selection of an amino acyl-tRNA and again in a step coupled to hydrolysis of EF1α·GTP. Molecular simulations estimate that this second proofreading step increases the fidelity of translation about 15-fold.

Nonsense Mutations Can Be Bypassed by Suppressing tRNA Mutations

As we have seen, a mutation that converts a codon normally encoding an amino acid into a stop codon will lead to premature termination of translation. Nonsense mutations, as they are called, result in a truncated protein that is usually nonfunctional. In genetic studies with the bacterium *E. coli*, it was discovered that the effect of a nonsense mutation can be suppressed by a second mutation in a tRNA gene. This occurs when the sequence in a tRNA gene that encodes the anticodon is changed to a triplet that is complementary

to a stop codon. If, for example, a nonsense mutation in a gene converted a UCG (serine) codon into a UAG (stop) codon, the stop may be read often enough to produce some full-length protein if the anticodon of a tRNA were changed to CUA, which can base-pair with the UAG stop codon. One way to do this would be to mutate the gene for $tRNA^{Tyr}$ in a way that changes its anticodon from GUA to CUA. Importantly, the mutant $tRNA^{Tyr}$ can still be recognized by the tyrosine aminoacyl-tRNA synthetase, since the anticodon sequence is not a necessary feature for recognition by the corresponding aminoacyl-tRNA synthetase. Cells that have both the original nonsense mutation and the second mutation in the anticodon of the $tRNA^{Tyr}$ gene consequently can insert a tyrosine at the position of the mutant stop codon, allowing protein synthesis to continue past the original nonsense mutation. This mechanism is not highly efficient, so translation of normal mRNAs with a UAG stop codon terminates at the normal position in most instances. If enough of the protein encoded by the original gene with the nonsense mutation is produced to provide its essential functions, the effect of the first mutation is said to be *suppressed* by the second mutation in the anticodon of the tRNA gene.

This mechanism of *nonsense suppression* is a powerful tool in genetic studies of bacteria. For example, it allows us to isolate mutant bacterial viruses that cannot grow in normal cells but can grow in cells expressing a nonsense-suppressing tRNA because the mutant virus has a nonsense mutation in an essential gene. Such mutant

viruses grown on nonsense-suppressing cells can then be used in experiments to analyze the function of the mutant gene by infecting normal cells that do not suppress the mutation and analyzing what step in the viral life cycle is defective in the absence of the mutant protein.

KEY CONCEPTS OF SECTION 5.6

Stepwise Synthesis of Proteins on Ribosomes

- Bacterial, archaeal, and eukaryotic ribosomes — the large ribonucleoprotein complexes on which translation occurs — consist of a small and a large subunit. Each subunit contains numerous different proteins and one major rRNA molecule (small or large). The large subunit also contains one accessory 5S rRNA in bacteria and archaea and two accessory rRNAs in eukaryotes (5S and 5.8S).
- Analogous rRNAs from many different species fold into quite similar three-dimensional structures containing numerous stems and loops, as well as binding sites for proteins, mRNAs, and tRNAs. Much smaller ribosomal proteins are associated with the periphery of the rRNAs.
- Of the two methionine tRNAs found in all cells, only one $(\mathrm{tRNA_i^{Met}})$ functions in initiation of translation.
- Each stage of translation — initiation, chain elongation, and termination — requires specific protein factors, including GTP-binding proteins that hydrolyze their bound GTP to GDP when a step has been completed successfully.
- During initiation, the ribosomal subunits assemble near the translation start site in an mRNA molecule on which a tRNA carrying the amino-terminal methionine $(\mathrm{Met\text{-}tRNA_i^{Met}})$ has base-paired with the start codon (see Figure 5-36).
- Chain elongation entails a repetitive four-step cycle: loose binding of an incoming aminoacyl-tRNA to the A site on the ribosome; tight binding of the correct aminoacyl-tRNA to the A site accompanied by release of the previously used tRNA from the E site; transfer of the growing polypeptide chain to the incoming amino acid catalyzed by large rRNA; and translocation of the ribosome to the next codon, thereby moving the peptidyl-tRNA in the A site to the P site and the now unacylated tRNA in the P site to the E site (see Figure 5-38).

- In each cycle of chain elongation, the ribosome undergoes two conformational changes monitored by two GTP-binding proteins. The first of these proteins (EF1α) permits tight binding of the incoming aminoacyl-tRNA to the A site and ejection of a tRNA from the E site, and the second (EF2) monitors translocation.
- Termination of translation is carried out by two types of termination factors: those that recognize stop codons and those that promote hydrolysis of peptidyl-tRNA (see Figure 5-39). Once again, correct recognition of a stop codon is monitored by a GTPase (eRF3).
- The efficiency of protein synthesis is increased by the simultaneous translation of a single mRNA by multiple ribosomes, forming a polyribosome or polysome. In eukaryotic cells, protein-mediated interactions bring the two ends of a polyribosome close together, thereby promoting the rapid recycling of ribosomal subunits, which further increases the efficiency of protein synthesis (see Figure 5-39b).

5.7 Viruses: Parasites of the Cellular Genetic System

We wrap up this chapter with a discussion of **viruses**, which are radically different from the organisms we've so far discussed, but that nevertheless depend on fundamental genetic processes. Viruses carry instructions encoded in DNA or RNA that are copied by polymerization using standard Watson-Crick base pairing, and their genes are expressed according to the universal genetic code. The viral genome can be considered to be a self-replicating genetic program. In addition, viruses can mutate and they can evolve through the process of natural selection. Thus viruses have an autonomous existence in terms of the biological informational that they carry, but just as the instructions of a computer program cannot fully come into being without a computer to run on, the genetic instructions of a virus need a cellular host to synthesize viral proteins and to replicate the viral genome. Viruses are categorized according to the type of nucleic acid that makes up their genome. RNA viruses, which usually replicate in the host-cell cytoplasm, have an RNA genome, and DNA viruses, which commonly replicate in the host-cell nucleus, have a DNA genome (see Figure 5-1). Viral genomes may be single or double stranded, depending on the specific type of virus. The entire infectious virus particle, called a **virion**, consists of nucleic acid encased in a shell of protein, known as the **capsid**, which both protects the viral nucleic acid and functions in the process of host-cell infection. The genomes of the

simplest known viruses only encode four proteins; the most complex can encode some two hundred proteins. In addition to their obvious importance as causes of disease, viruses are extremely useful as research tools in the study of basic biological processes, such as those discussed in this chapter.

Most Viral Host Ranges Are Narrow

The process of infection usually begins when a protein on the surface of the virion binds to a specific protein on the surface of the host cell that the virus hijacks for use as a receptor. This interaction is usually highly specific and thus limits the *host range* — the types of cells that a virus can infect — to a very narrow range of cell types in particular species.

A virus that infects only bacteria is called a **bacteriophage**, or simply a **phage**. Viruses that infect animal or plant cells are referred to generally as animal viruses or plant viruses. Most animal viruses have host ranges restricted to certain phyla, and some infect only closely related species, such as primates. Some animal viruses, such as vesicular stomatitis virus, can infect insects as well as many different types of mammals. For viruses that can grow not only in plants or animals but also in the insects that feed on them, the highly mobile insects can serve as vectors for transferring the virus between susceptible hosts. The host-cell range of some animal viruses is further restricted to a limited number of cell types

because only those cells have surface receptors to which the virions can attach. One example is poliovirus, which infects only cells in the intestine and, unfortunately for its host, motor neurons in the spinal cord, causing paralysis. Another is HIV-1, discussed further in this section, which infects cells called $CD4^+$ *T lymphocytes* that are essential for the immune response (see Chapter 24) as well as certain neurons and other cells of the central nervous system called *glial cells*.

Viral Capsids Are Regular Arrays of One or a Few Types of Protein

The viral capsid is usually composed of multiple copies of only one protein or a few different proteins, each of which is encoded by a single viral gene. Because of this structure, a virus is able to encode all the information for making a relatively large capsid in a small number of genes. This efficient use of genetic information is important because only a limited amount of DNA or RNA, and therefore a limited number of genes, can fit into a virion capsid.

Nature has found two basic ways of packaging a viral genome within a regular structure composed of multiple copies of capsid proteins. In some viruses, multiple copies of a single capsid protein form a *helical* structure that encloses and protects the viral RNA or DNA, which runs in a helical groove within the protein tube. Viruses with

such a helical structure, such as tobacco mosaic virus, have a rodlike shape (Figure 5-40a). The other major structural type is based on the *icosahedron*, a solid, approximately spherical object built of 20 identical faces (Figure 5-40b). Since each face is an equilateral triangle that must be composed of at least three protein subunits, an icosahedral capsid must be composed of at least 60 subunits. During infection, some icosahedral viruses interact with host-cell receptors via clefts between the capsid subunits. Others interact via long fibrous proteins extending from the vertices of the icosahedron.

FIGURE 5-40 Virion structures. (a) Helical tobacco mosaic virus. (b, *left*) Diagram of the structure of poliovirus, a small icosahedral virus, made of 20 equilateral triangular faces, one of which is outlined in red. Each face is composed of three outlined structural elements called *capsomeres*. The numbers show how five capsomeres associate at the 12 vertices of the icosahedron. (b, *right*) Space-filling model of poliovirus based on x-ray crystallography. The model is color-coded according to distance from the center of the virion, red farthest, blue closest. The virion binds to host cell receptors (not shown), which are long, narrow cell surface proteins that enter the blue “canyons” around each vertex. (c) Bacteriophage T4. (d) Influenza virus, an example of an enveloped virus.

Part (b) data from D. J. Filman et al., 1989. *EMBO J.* **8**:1567, PDB ID 2plv.

In many DNA bacteriophages, the viral DNA is located within an icosahedral *head* that is attached to a rodlike *tail*. During infection, viral proteins at the tip of the tail bind to host-cell receptors, and the viral DNA then passes down the tail into the cytoplasm of the host cell (Figure 5-40c).

In some viruses, a symmetrically arranged **nucleocapsid** composed of the viral genome associated with multiple copies of one or a few proteins is covered by an external membrane, or **viral envelope**, which consists mainly of a phospholipid bilayer but also contains one or more types of virus-encoded glycoproteins (Figure 5-40d). The phospholipids in the viral envelope are similar to those in the plasma membrane of an infected host cell. The viral envelope is, in fact, derived by budding from that membrane, but contains mainly viral glycoproteins, as we will discuss shortly.

Lytic Viral Growth Cycles Lead to Death of Host Cells

Although details vary among different types of viruses, those that exhibit a *lytic cycle* of growth proceed through the following stages:

1. *Adsorption* — Virion interacts with a host cell by binding of multiple copies of capsid protein to specific receptors on the

cell surface.

2. *Entry* — The virus enters the cytoplasm of the host cell. Membrane enveloped viruses may enter through the endocytic pathway described in Chapter 14 while others fuse directly with the host plasma membrane. Viruses with a protein capsid must enter cells through the endocytic pathway so as not to disrupt the integrity of the plasma membrane.
3. *Early gene expression* — The first viral genes to be expressed are usually involved in the replication of the viral genome and the efficient expression of viral structural genes. For positive strand RNA viruses, early genes are expressed by direct translation of the genomic RNA in the cytoplasm. For DNA viruses, viral DNA enters the cell nucleus where viral mRNAs are produced with the aid of the host-cell transcription machinery. Viral mRNAs are translated by the host-cell translation machinery.
4. *Genome replication* — Production of multiple copies of the viral genome is carried out either by viral proteins alone or with the help of host-cell proteins. RNA viruses usually replicate in the cytoplasm whereas DNA viruses must replicate within the nucleus.
5. *Structural gene expression* — The virus uses host cell machinery for transcription and translation of viral structural proteins. These include proteins of the nucleocapsid and abundant membrane glycoprotein for membrane enveloped viruses.
6. *Assembly* — Viral proteins and replicated genomes associate to form progeny virions in the cytoplasm.
7. *Release* — The host cell may rupture suddenly (**lysis**), releasing all the newly formed virions at once, or disintegrate gradually,

releasing the virions slowly. For membrane enveloped viruses the last stage of assembly involves entry into membrane bounded organelles the secretory pathy and then release from the cell by exocytosis or by budding directly from the plasma membrane.

We will use coronavirus, which is the cause of the COVID-19 pandemic, as an example to show how a lytic virus navigates the compartments of a eukaryotic cell. Note that the features of the coronavirus life cycle depicted in Figure 5-41 are governed by the basic properties of the coronavirus as a membrane enveloped virus with an RNA genome. Coronavirus begins entry into a target cell by binding of the spike protein of the viral envelope to a receptor protein on the surface of the host cell. Binding to the receptor allows the virus to enter endocytic vesicles which bud into the interior of the cell as described in Chapter 14. Within an endocytic compartment, the relatively low pH triggers a proteolytic cleavage of the viral spike protein, activating the spike protein for fusion of the viral membrane with the endosome membrane and releasing the nucleocapsid into the cytoplasm.

FIGURE 5-41 Lytic replication cycle of a membrane enveloped RNA coronavirus. Coronavirus has a genome of ~30 kb of single stranded RNA, encoding about 30 viral proteins. Within the virion, the RNA genome is in a complex with the viral nucleocapsid (N) protein forming a helical nucleocapsid. The nucleocapsid is packaged within the viral membrane whose major constituents are the membrane (M) and spike (S) proteins. Infection begins with adsorbtion of the virus to a target cell by binding of the S protein to a specific cell surface receptor (step 1), leading to engulfment into an endosome (step 2). The S protein can catalyze fusion of membranes after it has been activated by a proteolytic cleavage that takes place within the acidic interior of the endosome. S protein catalyzed fusion of the viral membrane with the membrane of the endosome enables the nucleocapsid to enter the cytoplasm (step 3). Host cell ribosomes in the cytoplasm recognize the viral genomic RNA as an mRNA and translate early sequences encoding the viral Replicase (step 4). The Replicase produces complementary copies of the genome that are acted upon by the Replicase to produce viral mRNAs for expression of the viral structural proteins as well as many copies of the full length viral RNA genome (step 5).

Translated viral N protein (step 6) assembles with newly replicated viral genomic RNA to form nucleocapsid complexes (step 7). At the same time, the viral membrane proteins M and S are translated and assembled in the membrane of the ER (step 8). In membranes derived from the ER, these viral membrane proteins assemble into a precursor of the viral membrane (step 9), which then envelopes the nucleocapsid as the final stage of viral assembly (step 10). Mature virions formed by budding into the interior of the ER are secreted from the cell by exocytosis (step 11), ready to carry out another round of cellular infection and growth.

Coronavirus is a plus stranded RNA virus, meaning the single stranded RNA genome can immediately engage host-cell ribosomes in the cytoplasm for translation of early viral gene products. The early genes of coronavirus encode a protein complex known as Replicase, which is responsible for replication of the viral RNA genome. Replicase, which contains an RNA template dependent RNA polymerase, first uses the RNA genome as a template to produce complementary RNA strands. These complementary strands, in turn, are used as templates for the production of more copies of the RNA genome as well as of viral mRNAs suitable for translation of the viral structural proteins. The translated viral nucleocapsid protein assembles with viral RNA to form mature helical nucleocapsid structures.

Meanwhile, coronavirus membrane structural proteins are synthesized on the ER membrane (see Chapter 13) and cluster in regions of ER membrane that are precursors of the viral membrane. Complete virions are assembled by envelopment of nucleocapsid by viral membrane as the virus buds into the interior of the ER. Finally,

the mature virions are released from the cell by exocytosis (see Chapter 14). Some membrane enveloped viruses form by a similar envelopment process but are released from the cell by budding directly from the plasma membrane, as shown in an electron micrographs of a cell infected with measles virus in Figure 5-42.

Thomas Deerinck, NCMIR/Science Source.

EXPERIMENTAL FIGURE 5-42 Release of progeny virions by budding. Membrane enveloped viruses are released from infected cells by budding from the plasma

membrane. In this transmission electron micrograph of a cell infected with measles virus, virion buds are clearly visible protruding from the cell surface. Measles virus is an enveloped RNA virus with a helical nucleocapsid.

We have seen that for RNA viruses, replication of the RNA genome and the production and translation of viral mRNAs can take place entirely within the cytoplasm. For DNA viruses, the DNA genome must enter the nucleus in order to be transcribed into viral mRNA and to be replicated by nuclear DNA polymerases. Soon after entry into a host cell, the viral DNA genome is transported into the cell nucleus through nuclear pores, as described in Chapter 13. Once inside the nucleus, the viral DNA is transcribed into RNA by the host's transcription machinery. Processing of the viral RNA primary transcript by host-cell enzymes yields viral mRNA, which is transported to the cytoplasm and translated into viral proteins. The early viral proteins are then transported back into the nucleus, where they collaborate with the cellular replication machinery to replicate viral DNA. Viral proteins that comprise the capsid are usually expressed later in the infection process. Association of the capsid proteins with the newly replicated viral DNA occurs in the nucleus, yielding mature progeny virions.

After the synthesis of hundreds to many thousands of new virions has been completed, depending on the type of virus and host cell, the host cells lyse, releasing all the virions at once, or the host cell releases the virions gradually as the cell progressively disintegrates.

Viral DNA Is Integrated into the Host-Cell Genome in Some Nonlytic Viral Growth Cycles

The genomes of a number of animal viruses can integrate into the host-cell genome. Among the most important of these are the **retroviruses**, which are enveloped viruses with a genome consisting of two identical strands of RNA. These viruses are so named because their RNA genome acts as a template for the formation of a DNA molecule — a flow of genetic information that is opposite to the more common transcription of DNA into RNA. In the retroviral life cycle (Figure 5-43), a viral enzyme called **reverse transcriptase** initially copies the viral RNA genome into single-stranded DNA that is complementary to the viral RNA; the same enzyme then catalyzes the synthesis of a complementary DNA strand. (This complex reaction is detailed in Chapter 7, where we consider closely related intracellular parasites called *retrotransposons*.) The resulting double-stranded DNA is integrated into the chromosomal DNA of the infected cell by an integrase enzyme in the virion. Finally, the integrated DNA, called a *provirus*, is transcribed by the host cell's own RNA polymerase into RNA, which is either translated into viral proteins or packaged within virion capsid proteins to form progeny virions that are released by budding from the host-cell membrane. Because most retroviruses do not kill their host cells, infected cells can replicate, producing daughter cells with integrated proviral

DNA. These daughter cells continue to transcribe the proviral DNA and bud progeny virions.

FIGURE 5-43 Retroviral life cycle. Retroviruses have a genome of two identical copies of single-stranded RNA and an outer envelope. Step 1: After viral glycoproteins in the retroviral envelope interact with a specific host-cell membrane protein, the envelope fuses directly with the plasma membrane, allowing entry of the nucleocapsid into the cytoplasm of the cell. Step 2: Viral reverse transcriptase and other proteins copy the viral ssRNA genome into a double-stranded DNA. Step 3: The viral dsDNA is transported into the nucleus and integrated into one of many possible sites in the host-cell chromosomal DNA. For simplicity, only one host-cell chromosome is depicted. Step 4: The integrated viral DNA (provirus) is transcribed by the host-cell RNA polymerase, generating viral mRNAs (dark red) and viral genomic RNA molecules (bright red). The host-cell machinery translates the viral mRNAs into glycoproteins and nucleocapsid proteins. Step 5: Progeny virions then assemble and are released by budding, as illustrated in Figure 5-42.

Some retroviruses contain cancer-causing genes (*oncogenes*), and cells infected by such retroviruses are oncogenically transformed into tumor cells. Studies of oncogenic retroviruses (mostly viruses of birds and mice) have revealed a great deal about the processes that lead to transformation of a normal cell into a cancer cell (see Chapter 25).

Among the known human retroviruses are human T-cell lymphotrophic virus (HTLV), which causes a form of leukemia, and human immunodeficiency virus (HIV-1), which causes acquired immune deficiency syndrome (AIDS). Both of these viruses can infect only specific cell types, primarily certain cells of the immune system and, in the case of HIV-1, some central nervous system neurons and glial cells. Only those cells have cell-surface receptors that interact with viral envelope proteins. Unlike most other retroviruses, HIV-1 eventually kills its host cells. The eventual death of large numbers of immune-system cells results in the defective immune response characteristic of AIDS.

Retroviruses, such as HIV-1, make a DNA replica of the information in viral RNA. The enzyme responsible for this copying reaction is reverse transcriptase, which functions similarly to DNA polymerase but uses the viral RNA as a template. Reverse transcriptase, encoded as a viral gene, lacks a proofreading activity and is much more error prone than cellular DNA polymerases. In this case, a low fidelity of replication works to the advantage of the virus because frequent

mutations in the viral capsid genes allow the virus to continually alter the antigens on the surface of the virion and thus evade the human immune system.

Some DNA viruses can also integrate into a host-cell chromosome. One example is the human papillomaviruses (HPVs), which most commonly cause warts and other benign skin lesions. These viruses replicate without integrating into a host-cell chromosome. However, the genomes of certain HPV serotypes occasionally integrate into the chromosomal DNA of infected cervical epithelial cells. Unlike retroviruses and temperate bacteriophages, this integration is not carried out by viral proteins, but rather is the consequence of host-cell DNA repair processes. Integration is a dead-end for HPV. The integrated viral DNA cannot replicate and generate progeny virions, but oncogenic (cancer-causing) viral proteins can be expressed from the integrated viral genome, initiating development of cervical cancer. A vaccine for the types of HPV associated with cervical cancer has been developed and can protect against the initial infection by these viruses, and consequently, against development of cervical cancer.

KEY CONCEPTS OF SECTION 5.7

Viruses: Parasites of the Cellular Genetic System

- Viruses are small packages of genetic information that can move from one cell to another and that depend on the host cell for their gene expression and replication.

Viral genomes may be either DNA (DNA viruses) or RNA (RNA viruses) and may be either single or double stranded.

- The capsid, which surrounds the viral genome, is composed of multiple copies of one or a small number of virus-encoded proteins. Some viruses also have an outer envelope, which is similar to the plasma membrane of the host cell but contains viral transmembrane proteins.
- Most animal and plant DNA viruses require host-cell nuclear enzymes to carry out transcription of the viral genome into mRNA and production of progeny genomes. In contrast, most RNA viruses encode enzymes that can transcribe the RNA genome into viral mRNA and produce new copies of the RNA genome.
- Host-cell ribosomes, tRNAs, and translation factors are used in the synthesis of all viral proteins in infected cells.
- Lytic viral infection entails adsorption, penetration, synthesis of viral proteins and progeny genomes (replication), assembly of progeny virions, and release of hundreds to thousands of virions, leading to death of the host cell (see Figure 5-41). Release of enveloped viruses occurs by budding through the host-cell plasma membrane (see Figure 5-42).
- Retroviruses are enveloped animal viruses containing a single-stranded RNA genome. After a host cell is penetrated, reverse transcriptase, a viral enzyme carried in the virion, converts the viral RNA genome into double-stranded DNA, which is integrated into chromosomal DNA by an integrase enzyme that enters the cell inside the virion (see Figure 5-43).
- Unlike infection by other retroviruses, HIV-1 infection eventually kills host cells, causing the defects in the immune response characteristic of AIDS.
- Tumor viruses, which contain oncogenes, may have an RNA genome (e.g., human T-cell lymphotrophic virus) or a DNA genome (e.g., human papillomaviruses). Integration of the genomes of these viruses into a host-cell chromosome can cause transformation of the host cell into a tumor cell.

Review the Concepts

1. What are Watson-Crick base pairs? Why are they important?
2. Preparing plasmid DNA (double stranded, circular) for sequencing involves annealing a complementary, short, single-stranded oligonucleotide DNA primer to one strand of the plasmid template. This is routinely accomplished by heating the plasmid DNA and primer to 90° C and then slowly bringing the temperature down to 25° C. Why does this protocol work?
3. What difference between RNA and DNA helps to explain the greater stability of DNA? What implications does this have for the function of DNA?
4. What are the major differences in the synthesis and structure of prokaryotic and eukaryotic mRNAs?

5. While investigating the function of a specific growth factor receptor gene from humans, researchers found that two types of proteins are synthesized from this gene. A larger protein containing a membrane-spanning domain recognizes growth factors at the cell surface, stimulating a specific downstream signaling pathway. In contrast, a related, smaller protein is secreted from the cell and binds available growth factor circulating in the blood, thus inhibiting the downstream signaling pathway. Speculate on how the cell synthesizes these disparate proteins.
6. How would a mutation in the poly(A)-binding protein gene affect translation? How would an electron micrograph of polyribosomes from such a mutant differ from the normal pattern?
7. What characteristic of DNA results in the requirement that some DNA synthesis be discontinuous? How are Okazaki fragments and DNA ligase used by the cell?
8. Eukaryotes have repair systems that prevent mutations due to copying errors and exposure to mutagens. What are the three excision-repair systems found in eukaryotes, and which one is responsible for correcting thymine-thymine dimers that form as a result of UV light damage to DNA?
9. DNA-repair systems are responsible for maintaining genomic fidelity in normal cells despite the high frequency with which mutational events occur. What type of DNA mutation is generated by (a) UV radiation and (b) ionizing radiation? Describe the system responsible for repairing each of these types of mutations in mammalian cells. Postulate why a loss of function in one or more DNA repair systems is present in many cancers.

10. What is the name given to the process that can repair DNA damage *and* generate genetic diversity? Briefly describe the similarities and differences of the two processes.
11. a. Which of the following DNA strands, the top or bottom, would serve as a template for RNA transcription if the DNA molecule were to unwind in the indicated direction?

    5′ ACGGACTGTACCGCTGAAGTCATGGACGCTCGA 3′

    3′ TGCCTGACATGGCGACTTCAGTACCTGCGAGCT 5′

    $\longrightarrow$

    Direction of DNA unwinding

    b. What would be the resulting RNA sequence (written $5' \rightarrow 3'$)?
12. Contrast prokaryotic and eukaryotic gene characteristics.
13. You have learned about the events surrounding DNA replication and the central dogma. Identify the steps associated with these processes that would be adversely affected in the following scenarios.
    a. Helicases unwind the DNA, but stabilizing proteins are mutated and cannot bind to the DNA.
    b. The mRNA molecule forms a hairpin loop on itself via complementary base pairing in an area spanning the AUG start site.
    c. The cell is unable to produce functional $\mathrm{tRNA_i^{Met}}$.
14. Use the accompanying key to determine the amino acid sequence of the polypeptide produced from the following DNA sequence. Intron sequences are highlighted. Note: Not all amino acids in the key will be used.

    5′ TTCTAAACGCATGAAGCACCGTCTCAGAGCCAGTGA 3′

    3′ AAGATTTGCGTACTTCGTGGCAGAGTCTCGGTCACT 5′

$\longrightarrow$

Direction of DNA unwinding

Met = AUG Phe = UUC Ser = AGC Tyr = UAC Val = GUC; GUA

15.

a. Look at the figure above. Explain why it is necessary for Okazaki fragments to be formed as the lagging strand is produced (instead of a continuous strand).
b. If the DNA polymerase in the figure above could bind only to the lower template strand, under what condition(s) would it be able to produce a leading strand?

16. The DNA repair systems preferentially target the newly synthesized strand. Why is this important?
17. Identify the specific types of point mutations below (you are viewing the direct DNA version of the RNA sequence).

    Original sequence: 5′ AUG TCA GGA CGT CAC TCA GCT 3′

    Mutation A: 5′ AUG TCA GGA CGT CAC TGA GCT 3′

    Mutation B: 5′ AUA TCA GGA CGT CAC TCA GCT 3′
18. The genome of a retrovirus can integrate into the host-cell genome. A number of retroviruses can infect certain types of human cells.
    a. What gene is unique to retroviruses, and why is the protein encoded by this gene absolutely necessary for maintaining the retroviral life cycle?

b. List two retroviruses that infect specific cell types, briefly describe the medical implications resulting from these infections, and describe why only certain cells are infected.

19. a. Detail the key differences between lytic and nonlytic viral infection and provide an example of each.

    b. Which of the following processes occurs in both lytic and nonlytic viral infections?

        i. Infected cell ruptures to release viral particles.

        ii. Viral mRNAs are transcribed by the host-cell translation machinery.

        iii. Viral proteins and nucleic acids are packaged to produce virions.

CHAPTER 6

Molecular Genetic Techniques

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman

Genetic modifications make it possible to locate a specific cell type within the body of a living mouse. Scientists can label cells of the immune system by generating a transgenic mouse carrying the gene for insect luciferase expressed from the CD2 promoter, which is specifically expressed in T cells. After injection of the bioluminescent substrate for luciferase,

the light emitted through the skin is imaged for 30 seconds. T cells can be seen located in the lymph nodes (LNs), the thymus (thy), and the spleen (spl).

OUTLINE

6.1 Using Genetic Analysis of Mutations to Identify and Study Genes
6.2 DNA Cloning and Characterization
6.3 Using Sequence Information to Identify Genes and Deduce Their Function
6.4 Locating and Identifying Genes That Specify Human Traits
6.5 Using Cloned DNA Fragments to Study Gene Expression
6.6 Altering the Function of Specific Genes by Design

In the field of molecular cell biology, we seek to understand the biological behavior of cells in terms of the underlying chemical and molecular mechanisms. Most often, cell biologists investigating some molecular process focus on the function of particular proteins or sets of proteins. They set out to answer a set of fundamental questions: What is the function of the protein in the context of a living cell? What is the biochemical function of the purified protein? Where is the protein located within the cell? When and where is the protein expressed? How is it related to other proteins? And how did the function of the protein arise during evolution? The answers to these questions almost always come from the study and manipulation of the gene that encodes the particular protein. In the first part of this chapter, we consider strategies for identifying and isolating genes of interest. We then consider strategies for

determining the cellular function of the gene product (Figure 6-1). These strategies rely on experimental methods for manipulating genes.

FIGURE 6-1 Genetic and genomic analysis is central to understanding cell function at the molecular level. The general strategy for understanding the function of the constituent parts of a cell is to first identify and isolate a gene. This process begins with a mutant organism, a purified protein, or the identification of a protein-coding sequence by analysis of genomic sequence databases. The actual gene is isolated either from a DNA library of clones or by amplifying the specific gene sequence from genomic DNA. The gene sequence can be used to identify other similar gene sequences in genomic databases, providing insight into the general function of the gene and how it evolved. Once a cloned gene is isolated, it can be manipulated to produce large quantities of the protein it encodes for biochemical experiments and to design probes for studies of where and when the protein is expressed in an organism. Alternatively, a cloned gene can be inactivated by one of various techniques and used to generate mutant cells or organisms. By examining the phenotypic consequences of mutations that inactivate a particular gene, geneticists are able to connect knowledge about the sequence, structure, and biochemical activity of the encoded protein to its function in the context of a living cell or multicellular organism.

Classically, proteins with important cellular functions were discovered either by purifying a protein with a relevant biochemical activity or by isolating an appropriate mutant. An excellent example showing how these two approaches can mutually reinforce one another was the discovery of NSF, a key protein required for vesicle trafficking in the secretory pathway, described in Chapter 14. The mammalian NSF protein was purified using a biochemical assay for fusion of transport vesicles with their target membrane. Meanwhile, a mutation in the yeast gene known as *sec18* was identified in a genetic screen for mutants with a defect in protein secretion. Eventually the genetic and biochemical approaches were shown to have converged on the same gene when the yeast gene defective in the *sec18* mutant was shown to be highly similar in sequence to the mammalian gene that encodes the NSF protein.

Today the complete genome sequences of the human and all of the major experimental organisms are known, and the pace at which genes can be identified and studied has accelerated enormously. Because gene sequences and the sequences of the encoded proteins can be obtained from genomic sequences, almost the entire repertoire of encoded proteins is already known for most experimental organisms. Thus gene sequences of interest can now be readily and automatically identified from the chromosomal location of a mutation or just a short segment of the amino acid sequence of a purified protein. Moreover, genes worthy of study can be identified entirely from sequence information by comparing the

genome sequences from different organisms. Using this approach, investigators can study the function of a human gene that is implicated in cancer, for example, by manipulating the corresponding gene of similar sequence in the mouse or even in the fruit fly or in yeast if a similar gene is present.

6.1 Using Genetic Analysis of Mutations to Identify and Study Genes

As described in Chapter 5, the information encoded in the DNA sequence of genes specifies the sequence — and therefore the structure and function — of every protein molecule in a cell. The power of genetics as a tool for studying cells and organisms lies in the ability of researchers to make a change in some gene and then evaluate the effect on a living organism. Geneticists expose organisms to an agent that induces mutations, then search for mutant organisms that are defective in a process of interest. Genetic analyses of mutants defective in a particular process can reveal (1) genes required for the process to occur, (2) the order in which gene products act in the process, and (3) whether and how the proteins encoded by different genes interact with one another. Before we look more closely at genetic studies of this type, let's first review some basic genetic terms used throughout our discussion.

The different forms or variants of a gene are referred to as **alleles**. Geneticists commonly refer to the numerous naturally occurring genetic variants that exist in populations, particularly human populations, as alleles. The term **mutation** is usually reserved for a recent change in an allele, such as after treatment of an

experimental organism with a **mutagen**, an agent that causes a heritable change in the DNA sequence.

Strictly speaking, the particular set of alleles for all the genes carried by an individual constitutes its **genotype**. However, this term is most often used in a more restricted sense to denote the alleles of a particular gene or genes under examination. For experimental organisms, the term **wild type** is often used to designate a standard genotype for use as a reference in breeding experiments. Thus the normal, nonmutant allele is usually designated as the wild type. Because of the enormous allelic variation that naturally exists in human populations, the term *wild type* usually denotes an allele that is present at a much higher frequency than any of the other possible alternatives.

Geneticists draw an important distinction between the *genotype* and the *phenotype* of an organism. The term **phenotype** refers to all the physical attributes or traits of an individual that are the consequence of a given genotype. In practice, however, the term *phenotype* is usually used to denote the consequences that result from the particular alleles that are under experimental study. Readily observable phenotypic characteristics are critical in the genetic analysis of mutations.

Recessive and Dominant Mutant Alleles Generally Have Opposite Effects on Gene Function

A fundamental genetic difference between experimental organisms is whether their cells carry two copies of each chromosome or only one copy of each chromosome. The former are referred to as *diploid*; the latter as *haploid*. Most complex multicellular organisms (e.g., fruit flies, mice, humans) are diploid, whereas many simple, unicellular organisms are haploid. Some organisms, notably the yeast *Saccharomyces cerevisiae*, can exist in either haploid or diploid states. The normal cells of some organisms, both plants and animals, carry more than two copies of each chromosome and are thus designated *polyploid*. Moreover, cancer cells begin as diploid cells, but through the process of transformation into cancer cells can gain extra copies of one or more chromosomes and are thus designated as *aneuploid*. Our discussion of genetic techniques and analysis relates to diploid organisms, including diploid yeasts.

Although many different alleles of a gene might be present in a population, any individual diploid organism will carry two copies of each gene and thus at most can have two different alleles. A diploid individual with two different alleles is **heterozygous** for a gene, whereas a diploid individual that carries two identical alleles is **homozygous** for a gene. A mutant allele is **recessive** if both alleles must be mutant in order for the mutant phenotype to be observed;

that is, the individual must be homozygous for the mutant allele to show the mutant phenotype. In contrast, a mutant allele is **dominant** if the mutant phenotype can be observed in a heterozygous individual carrying one mutant and one wild-type allele (Figure 6-2).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 6-2 Effects of dominant and recessive mutant alleles on phenotype in diploid organisms. A single copy of a dominant mutant allele is sufficient to produce a mutant phenotype, whereas both copies of a recessive mutant allele must be present to cause a mutant phenotype. Recessive mutations usually cause a loss of function; dominant mutations usually cause a gain of function or an altered function.

Whether a mutant allele is recessive or dominant provides valuable information about the function of the affected gene and the nature of the causative mutation. Recessive alleles usually result from a mutation that inactivates the affected gene, leading to a partial or complete *loss of function*. Such recessive mutations may remove part of the gene or the entire gene from the chromosome, disrupt expression of the gene, or alter the structure of the encoded protein, thereby altering its function. Conversely, dominant alleles are often the consequence of a mutation that causes some kind of *gain of function*. Such dominant mutations may increase the activity of the

encoded protein, confer a new function on it, or lead to a new spatial or temporal pattern of expression.

In some rare cases, dominant mutations are associated with a loss of function. For instance, some genes are *haploinsufficient*, in that removing or inactivating one of the two alleles of such a gene leads to a mutant phenotype because not enough gene product is made. In other rare instances, a dominant mutation in one allele may lead to a structural change in the protein that interferes with the function of the wild-type protein encoded by the other allele. This type of mutation, referred to as a *dominant-negative*, produces a phenotype similar to that obtained from a loss-of-function mutation.

Some alleles can exhibit both recessive and dominant properties. In such cases, statements about whether an allele is dominant or recessive must specify the phenotype. For example, the allele of the hemoglobin gene that produces sickle cell disease, designated Hb^s, has more than one phenotypic consequence. Individuals who are homozygous for this allele (Hb^s/Hb^s) have debilitating anemia caused by sickle-cell disease, but heterozygous individuals (Hb^s/Hb^a) do not have the disease. Therefore, Hb^s is *recessive* for the trait of sickle-cell disease. On the other hand, heterozygous (Hb^s/Hb^a) individuals are more resistant to malaria than are homozygous (Hb^a/Hb^a) individuals, revealing that Hb^s is *dominant* for the trait of malaria resistance. ■

As described in Chapter 5, spontaneous mutations continually arise as a result of chemical and radiation damage to DNA and of errors in DNA replication. In genetic screens of experimental organisms, it is usually desirable to increase the frequency of mutations by controlled application of a chemical mutagen. A mutagen commonly used in experimental organisms is ethylmethane sulfonate (EMS), which can chemically modify guanine bases in DNA, ultimately leading to the conversion of a G·C base pair into an A·T base pair. The alteration of only a single base pair in the sequence of a gene is known as a **point mutation**. As will be described in Section 6.3, a point mutation can cause either a loss of function or a gain of function in a gene depending on the type of mutation and where it occurs in a gene sequence.

Segregation of Mutations in Breeding Experiments Reveals Whether They Are Dominant or Recessive

To see how Mendelian genetics is used to test whether an allele is dominant or recessive, we must first review the type of cell division that gives rise to gametes (sperm and egg cells in animals). Whereas the body (somatic) cells of most multicellular organisms divide by mitosis, the germ cells that give rise to gametes undergo meiosis. Like somatic cells, before meiosis germ cells are diploid, containing two homologs of each morphological type of chromosome. The two

homologs are descended from different parents, and thus their genes may exist in different allelic forms. Figure 6-3 depicts the major events in mitotic and meiotic cell division. In mitosis, DNA replication is always followed by cell division, yielding two diploid daughter cells. In meiosis, *one* round of DNA replication is followed by *two* separate cell divisions, yielding haploid (1*n*) cells known as gametes that contain only one chromosome of each homologous pair. The apportionment, or **segregation**, of the replicated homologous chromosomes to daughter cells during the first meiotic division is random, and different chromosomes segregate independently of one another, yielding gametes with different mixes of paternal and maternal chromosomes.

FIGURE 6-3 Comparison of mitosis and meiosis. Both somatic cells and pre-meiotic germ cells have two copies of each chromosome (2*n*), one inherited from the mother and one from the father. In mitosis, the replicated chromosomes, each composed of two sister chromatids, align at the cell center in such a way that both daughter cells receive a maternal and a paternal homolog of each morphological type of chromosome. During the first *meiotic* division, however, each replicated chromosome pairs with its homologous partner at the cell center; this pairing off is referred to as *synapsis*, and crossing over between homologous chromosomes is evident at this stage. One replicated chromosome of each morphological type then goes into each daughter cell. The resulting cells undergo a second division without intervening DNA replication, so that one of the sister chromatids of each morphological type

is apportioned to the daughter cells. In the second meiotic division, the alignment of chromatids and their equal segregation into daughter cells is the same as in mitotic division. The alignment of pairs of homologous chromosomes in metaphase I is random with respect to other chromosome pairs, resulting in a mix of paternally and maternally derived chromosomes in each daughter cell.

The key to determining whether an allele is dominant or recessive is to construct a heterozygote by breeding experiments. As a way to avoid unwanted complications in this process, geneticists usually strive to begin with strains of organisms that are homozygous for the genes under examination. In such *true-breeding* strains, every individual will receive the same allele from each parent, and therefore the composition of alleles will not change from one generation to the next. When a true-breeding mutant strain is mated to a true-breeding wild-type strain, all the first filial (F_1) progeny will be heterozygous (Figure 6-4). If the F_1 progeny exhibit the mutant trait, then the mutant allele is dominant; if the F_1 progeny exhibit the wild-type trait, then the mutant allele is recessive. Further crossing between F_1 individuals will also reveal different patterns of inheritance according to whether the mutation is dominant or recessive. When F_1 individuals that are heterozygous for a dominant allele are crossed among themselves, three-fourths of the resulting F_2 progeny will exhibit the mutant trait. In contrast, when F_1 individuals that are heterozygous for a recessive allele are crossed among themselves, only one-fourth of the resulting F_2 progeny will exhibit the mutant trait.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 6-4 Segregation patterns of dominant and recessive mutations in crosses between true-breeding strains of diploid organisms. All the offspring in the first (F_1) generation are heterozygous. If the mutant allele is dominant, the F_1 offspring will exhibit the mutant phenotype, as in part (a). If the mutant allele is recessive, the F_1 offspring will exhibit the wild-type phenotype, as in part (b). Crossing of the F_1 heterozygotes among themselves also produces different segregation ratios for dominant and recessive mutant alleles in the F_2 generation. Diploid organisms with the mutant phenotype are yellow and diploid organisms with a normal phenotype are blue.

As noted earlier, the yeast *S. cerevisiae*, an important experimental organism, can exist in either a haploid or a diploid state. In these unicellular eukaryotes, crosses between haploid cells can determine whether a mutant allele is dominant or recessive. Haploid yeast cells, which carry one copy of each chromosome, can be of two different mating types, known as **a** and α. Haploid cells of opposite mating type can mate to produce **a**/α diploids, which carry two copies of each chromosome. If a new mutation with an observable phenotype is isolated in a haploid strain, the mutant strain can be mated to a wild-type strain of the opposite mating type to produce **a**/α diploids that are heterozygous for the mutant allele. If these diploids exhibit the mutant trait, then the mutant allele is dominant, but if the diploids exhibit the wild-type trait, then the mutant allele is recessive. When **a**/α diploids are placed under starvation conditions, the cells undergo meiosis, each giving rise to a tetrad of four haploid spores, two of type **a** and two of type α. A heterozygous diploid cell yields two spores carrying the mutant allele and two carrying the wild-type allele (Figure 6-5). Under appropriate

conditions, yeast spores will germinate, producing vegetative haploid strains of both mating types.

FIGURE 6-5 Segregation of alleles in yeast. Haploid *Saccharomyces* cells of opposite mating type (i.e., one of mating type **a** and one of mating type α) can mate to produce an **a**/α diploid. If one haploid carries a dominant wild-type allele and the other carries a recessive mutant allele of the same gene, the resulting heterozygous diploid will express the dominant trait. Under certain conditions, a diploid cell will form a tetrad of four haploid spores. Two of the spores in the tetrad will express the recessive trait and two will express the dominant trait. Yeast with the mutant trait are shown in yellow and yeast with a normal phenotype are shown in blue.

Conditional Mutations Can Be Used to Study Essential Genes in Yeast

Procedures called *genetic screens* are used to identify and isolate mutants. These procedures depend on whether the experimental organism is haploid or diploid and, if the latter, whether the mutation is recessive or dominant. Genes that encode proteins essential for life are among the most interesting and important ones to study. Since phenotypic expression of a mutation in an essential gene leads to death of the individual, clever genetic screens are needed to isolate and maintain organisms with a lethal mutation.

In haploid yeast cells, essential genes can be studied through the use of *conditional mutations*, so called because the mutant phenotype is exhibited under certain conditions but not others. Among the most common conditional mutations are *temperature-sensitive mutations*, which are useful in organisms, such as bacteria and lower eukaryotes, that can grow at a range of temperatures. For instance, a missense mutation may cause the resulting mutant protein to be less stable at certain temperatures, such that the protein is fully functional at one temperature (e.g., 23 °C) but begins to denature and is thus inactive at another temperature (e.g., 36 °C), whereas the normal protein would be fully stable and functional at both temperatures. A temperature at which the mutant phenotype is observed is called *nonpermissive*; a *permissive* temperature is one at which the mutant phenotype is not observed even though the

mutant allele is present. Thus mutant strains can be maintained at a permissive temperature and then grown at a nonpermissive temperature for analysis of the mutant phenotype.

An example of a particularly important screen for temperature-sensitive mutants in the yeast *S. cerevisiae* comes from the studies of L. H. Hartwell and colleagues in the late 1960s and early 1970s. They set out to identify genes important in regulation of the cell cycle (during which a cell synthesizes proteins, replicates its DNA, and then undergoes mitotic cell division). Exponential growth of a single yeast cell for 20–30 cell divisions forms a visible yeast colony on solid agar medium. Because mutants with a complete block in the cell cycle would not be able to form colonies, conditional mutants were required to study mutations that affect this basic cellular process. To screen for such mutants, the researchers first exposed yeast cells to mutagens and then identified mutant yeast cells that could grow normally at 23 °C, but could not form a colony when placed at 36 °C (Figure 6-6a).

EXPERIMENTAL FIGURE 6-6 Haploid yeast cells carrying temperature-sensitive lethal mutations can be maintained at permissive temperature and analyzed at nonpermissive temperature. (a) Genetic screen for temperature-sensitive cell division cycle (cdc) mutants in *S. cerevisiae*. Yeast cells that grow and form colonies at 23 °C (permissive temperature) but not at 36 °C (nonpermissive temperature) may carry a lethal mutation that blocks cell division. See L. H. Hartwell, 1967, *J. Bacteriol.* **93**:1662. (b) The subset of temperature-sensitive mutants that have a block in the cell cycle can be identified by an arrest at the nonpermissive temperature at a uniform stage of the cell cycle. Shown here are representations of wild-type yeast and two different temperature-sensitive mutants after

incubation at the nonpermissive temperature for 6 hours. Wild-type cells, which continue to grow, can be seen with all different sizes of buds, reflecting different stages of the cell cycle. In contrast, *cdc28* mutants arrest at a point before emergence of a new bud and therefore appear as unbudded cells, while the *cdc7* mutants, which arrest just before separation of the mother cell and bud (emerging daughter cell), appear as cells with large buds.

Once temperature-sensitive mutants were isolated, further analysis revealed that some indeed were defective in cell division. In *S. cerevisiae*, cell division occurs through a budding process, and the size of the bud, which is easily visualized by light microscopy, indicates a cell's position in the cell cycle. Each of the mutants that could not grow at 36 °C was examined by microscopy after several hours at the nonpermissive temperature. Examination of many different temperature-sensitive mutants revealed a set that exhibited a distinct block in the cell cycle. These mutants were therefore designated *cdc (c*ell *d*ivision *c*ycle) *mutants*. Importantly, these yeast mutants did not simply fail to grow, as they might have if they carried a mutation affecting general cellular metabolism. Rather, at the nonpermissive temperature, the mutants grew normally for part of the cell cycle, but then arrested at a particular stage of the cell cycle, so that many cells at that stage were seen (Figure 6-6b). Most cdc mutations in yeast are recessive; that is, when haploid cdc strains are mated to wild-type haploids, the resulting heterozygous diploids are neither temperature sensitive nor defective in cell division.

Recessive Lethal Mutations in Diploids Can Be Identified by Inbreeding and Maintained in Heterozygotes

In diploid organisms, phenotypes resulting from recessive mutations can be observed only in individuals that are homozygous for the mutant alleles. Yet exposure of a diploid organism to a mutagen typically changes only one of the two copies of a given gene, yielding heterozygous mutants. Thus genetic screens must include inbreeding steps to generate progeny that are homozygous for the mutant allele. The geneticist H. Muller developed a general and efficient procedure for carrying out such inbreeding experiments in the fruit fly *Drosophila*. By using such procedures, recessive lethal mutations in *Drosophila* and other diploid organisms can be maintained in heterozygous individuals and their phenotypic consequences analyzed in homozygotes.

The Muller approach was used to great effect by Christiane Nüsslein-Volhard and Eric Wieschaus, who systematically screened for recessive lethal mutations affecting embryogenesis in *Drosophila*. The two researchers screened for dead homozygous embryos carrying recessive lethal mutations, then examined the dead embryos under the microscope for specific morphological defects. Current understanding of the molecular mechanisms underlying the development of multicellular organisms is based, in

large part, on the detailed picture of embryonic development revealed by characterization of these *Drosophila* mutants.

Complementation Tests Determine Whether Different Recessive Mutations Are in the Same Gene

Researchers using the classical genetic approach to studying a particular cellular process often isolate multiple recessive mutations that produce the same phenotype. A common test for determining whether these mutations are in the same gene or in different genes exploits the phenomenon of *genetic complementation*; that is, restoration of the wild-type phenotype by mating two different mutants. If two recessive mutations, *a* and *b*, are in the *same* gene, then a diploid organism carrying one *a* allele and one *b* allele will exhibit the mutant phenotype because neither allele provides a functional copy of the gene. In contrast, if mutations *a* and *b* are in *separate* genes, then heterozygotes carrying a single copy of each mutant allele will not exhibit the mutant phenotype because a wild-type allele of each gene is also present. In this case, the mutations are said to *complement* each other. Complementation analysis cannot be performed on dominant mutations because the phenotype conferred by the mutant allele is displayed even in the presence of a wild-type allele of the gene.

Complementation analysis of a set of mutants exhibiting the same phenotype can distinguish the individual genes in a set of functionally related genes, all of which must function to produce a given phenotypic trait. For example, the screen for cdc mutations in the yeast *S. cerevisiae* described previously yielded many recessive, temperature-sensitive mutants that appeared to be arrested at the same cell cycle stage. To determine how many genes were affected by these mutations, Hartwell and his colleagues performed complementation tests on all of the pair-wise combinations of their cdc mutants, following the general protocol outlined in Figure 6-7. These tests organized more than 100 cdc mutations into about 20 different *CDC* genes. The subsequent molecular characterization of the *CDC* genes and their encoded proteins, as described in detail in Chapter 19, has provided a framework for understanding how cell division is regulated in organisms ranging from yeast to humans.

EXPERIMENTAL FIGURE 6-7 Complementation analysis determines whether recessive mutations are in the same or different genes. Complementation tests in yeast are performed by mating haploid **a** and α cells carrying different recessive mutations to produce diploid cells. In the analysis of cdc mutations, pairs of different haploid temperature-sensitive cdc strains were systematically mated and the resulting diploids tested for growth at the permissive and nonpermissive temperatures. In this hypothetical example, the *cdcX*

and *cdcY* mutants complement each other and thus have mutations in different genes, whereas the *cdcX* and *cdcZ* mutants have mutations in the same gene.

Double Mutants Are Useful in Assessing the Order in Which Proteins Function

By careful analysis of mutant phenotypes associated with a particular cellular process, researchers can often deduce the order in which a set of genes and their protein products function. Two general types of processes are amenable to such analysis: (1) biosynthetic pathways in which a precursor material is converted via one or more intermediates to a final product, and (2) signaling pathways that regulate other processes and involve the flow of information rather than chemical intermediates.

Ordering of Steps in Biosynthetic Pathways

A simple example of the first type of process is the biosynthetic pathway for secreted proteins discussed in Chapter 14. In the secretory pathway, proteins move from their site of synthesis on the rough endoplasmic reticulum (ER) to the Golgi complex, then to secretory vesicles, and finally to the cell surface. The genetic analysis of this pathway in *S. cerevisiae* began, like the analysis of cell cycle mutants, with the isolation of temperature-sensitive mutants

that blocked different steps along the secretory pathway. These mutants could be categorized according to the type of organelle that accumulated at the nonpermissive temperature. For example, at the nonpermissive temperature, *sec12* mutants accumulated membranes that looked like ER membranes, whereas *sec4* mutants accumulated secretory vesicles. It was possible to establish the order in which the genes act along the pathway by analysis of double mutants. By constructing a double mutant that contained both *sec12* and *sec4*, it was conclusively shown that the *sec12* mutant acts earlier in the pathway than *sec4* because the double mutant accumulates ER membranes and not secretory vesicles. The general logic by which double mutants defective in two steps in a biosynthetic pathway are useful in ordering such pathways is shown in Figure 6-8a.

A mutation in A accumulates intermediate 1.

A mutation in B accumulates intermediate 2.

PHENOTYPE OF DOUBLE MUTANT:	A double mutation in A and B accumulates intermediate 1.
INTERPRETATION:	The reaction catalyzed by A precedes the reaction catalyzed by B.

(b) Analysis of a signaling pathway

A mutation in A gives **repressed** reporter expression.

A mutation in B gives **constitutive** reporter expression.

PHENOTYPE OF

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 6-8 Analysis of double mutants can often order the steps in biosynthetic or signaling pathways. When mutations in two different genes affect the same cellular process but produce distinctly different phenotypes, the phenotype of the double mutant can often reveal the order in which the two genes must function. (a) In the case of mutations that affect the same biosynthetic pathway, a double mutant will accumulate the intermediate immediately preceding the step catalyzed by the protein that acts earlier in the wild-type organism. (b) Double-mutant analysis of a signaling pathway is possible if two mutations have opposite effects on expression of a reporter gene.

Ordering Steps of Signaling Pathways

As we will learn in later chapters, the expression of many eukaryotic genes is regulated by signaling pathways that are initiated by

extracellular hormones, growth factors, or other signals. Such signaling pathways may include numerous components, and double-mutant analysis can often provide insight into the functions and interactions of these components. The only prerequisite for obtaining useful information from this type of analysis is that the two mutations must have very different, or even opposite, effects on the output of the same regulated pathway as measured by expression of a reporter gene. Most commonly, one mutation represses expression of a particular reporter gene even when the signal is present, while another mutation results in the expression of that reporter gene even when the signal is absent (i.e., constitutive expression). As illustrated in Figure 6-8b, two simple regulatory mechanisms are consistent with such single mutants, but the double-mutant phenotype can distinguish between them. Thus the observed phenotype of the double mutant provides information about the order in which the proteins act and whether they are positive or negative regulators.

This general approach has enabled geneticists to delineate many of the key steps in a variety of different regulatory pathways, setting the stage for more specific biochemical assays.

Note that this technique differs from the complementation analysis just described in that both dominant and recessive mutants can be subjected to double-mutant analysis. When two recessive mutations

are tested, the double mutant created must be *homozygous* for both mutations.

Genetic Suppression and Synthetic Lethality Can Reveal Interacting or Redundant Proteins

Two other types of genetic analysis can provide additional clues about how proteins that function in the same cellular process may interact with one another in the living cell. Both of these methods, which are applicable in many experimental organisms, involve the use of double mutants in which the phenotypic effects of one mutation are changed by the presence of a second mutation.

Suppressor Mutations

The first type of analysis is based on *genetic suppression*. To understand this phenomenon, suppose that point mutations lead to structural changes in one protein (A) that disrupt its ability to associate with another protein (B) involved in the same cellular process. Similarly, mutations in protein B lead to small structural changes that inhibit its ability to interact with protein A. Assume, furthermore, that the normal functioning of proteins A and B depends on their interacting. In theory, a specific structural change in protein A might be suppressed by compensatory changes in

protein B, allowing the mutant proteins to interact. In the rare cases in which such suppressor mutations occurred, strains carrying both mutant alleles would be normal, whereas strains carrying only one or the other mutant allele would have a mutant phenotype (Figure 6-9a).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 6-9 Mutations that result in genetic suppression or synthetic lethality reveal interacting or redundant proteins. (a) The observation that double mutants with two

defective proteins (A and B) have a wild-type phenotype but that single mutants have a mutant phenotype indicates that the function of each protein depends on interaction with the other. (b) The observation that double mutants have a more severe phenotypic defect than single mutants is also evidence that two proteins (e.g., subunits of a heterodimer) must interact to function normally. (c) The observation that a double mutant is nonviable but that the corresponding single mutants have the wild-type phenotype indicates that two proteins function in redundant pathways to produce an essential product.

The observation of genetic suppression in yeast strains carrying a mutant actin allele (*act1-1*) and a second mutation in another gene (*sac6*) provided early evidence for a direct interaction in vivo between the proteins encoded by the two genes. Later biochemical studies showed that these two proteins — Act1 and Sac6 — do indeed interact in the construction of functional actin structures within the cell.

Synthetic Lethal Mutations

Another phenomenon, called *synthetic lethality*, produces a phenotypic effect opposite to that of suppression. In this case, the deleterious effect of one mutation is greatly exacerbated (rather than suppressed) by a second mutation in a related gene. One situation in which such synthetic lethal mutations can occur is illustrated in Figure 6-9b. In this example, a heterodimeric protein is partially, but not completely, inactivated by mutations in either one of its nonidentical subunits. However, in double mutants carrying specific mutations in the genes encoding both subunits, little interaction between subunits occurs, resulting in severe phenotypic

effects. Synthetic lethal mutations can also reveal nonessential genes whose encoded proteins function in redundant pathways for producing an essential cell component. As depicted in Figure 6-9c, if either pathway alone is inactivated by a mutation, the other pathway will be able to supply the needed product. However, if both pathways are inactivated at the same time, the essential product cannot be synthesized, and the double mutants will be nonviable.

Global Analysis of Double Mutant Combinations Can Reveal Networks of Gene Functions

In the preceding sections we have seen how evaluation of the phenotype of double mutants can provide information about whether two genes participate in the same process or in redundant processes. We have also seen how double mutants can be used to determine the order of function for genes that participate in the same biosynthetic or regulatory pathway. The consequences of double mutants can usually be interpreted in more than one way, and the phenotype of any particular double mutant rarely provides a definitive conclusion about how the participating genes interact. However, when pair-wise combinations of double mutants from large sets of genes are examined together, convincing patterns of gene interactions can emerge.

The first comprehensive analysis of double mutants on a genome-wide scale was performed in *S. cerevisiae,* which has a total of about 6000 genes. Mutations in the approximately 1000 essential genes were obtained as temperature-sensitive alleles as described previously for *cdc* mutants, and the 5000 genes that are not essential were deleted, as described in Section 6.6. Using an automated system to perform genetic crosses, almost every possible double mutant was constructed and its phenotype compared to that of each of the single-component mutants. Computer algorithms determined the type and strength of genetic interaction based on the logic outlined previously. These algorithms produced a two-dimensional map of genetic interactions that clusters genes according to how closely related their functions are (Figure 6-10). Remarkably, when looking at the genes for which something is already known about their function, this interaction map, based only on information from the phenotype of double mutants, closely matches the known organization of metabolic and cell biologic processes. Importantly, for the many genes whose function is still unknown, their placement on the interaction map provides important clues to their function that may guide future biochemical and genetic studies. Methods using CRISPR-Cas9 now enable mutations to be produced in mammalian cells, as described in Section 6.6. These methods should allow similar large-scale gene interaction networks to be mapped in human cells.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 6-10 Gene Interaction Network for *S. cerevisiae*. The approximately 6000 genes of *S. cerevisiae* were tested in every possible pair-wise combination (a total of 2.3×10^7 double mutants were constructed). The relationships between genes were then arranged based on the type and strength of their genetic interactions by a computer algorithm. (a) In this global map of gene interactions, each point represents a single *S. cerevisiae* gene and the length of the segments connecting genes represents the degree to which genes display similar genetic interactions, with genes that exhibit the most closely related functions clustered most closely together. (b) A sample of genes of known function, color coded according to their cellular function, are placed on the global map of gene interactions. Importantly, genes known to be involved in the same process are in close proximity on the genetic interaction map.

KEY CONCEPTS OF SECTION 6.1

Genetic Analysis of Mutations to Identify and Study Genes

- Diploid organisms carry two copies (alleles) of each gene, whereas haploid organisms carry only one copy.
- Recessive mutations often lead to a loss of function, which is masked if a wild-type allele of the gene is present. For the mutant phenotype to be observed, both alleles must carry the mutation.
- Dominant mutations lead to a mutant phenotype in the presence of a wild-type allele of the gene. The phenotypes associated with dominant mutations often represent a gain of function.
- In meiosis, a diploid cell undergoes one DNA replication and two cell divisions, yielding four haploid cells in which maternal and paternal chromosomes and their associated alleles are randomly assorted (see Figure 6-3).
- Dominant and recessive mutations exhibit characteristic segregation patterns in genetic crosses (see Figure 6-4).
- In haploid yeast, temperature-sensitive mutations are particularly useful for identifying and studying genes essential to survival.
- The number of functionally related genes involved in a process can be defined by complementation analysis (see Figure 6-7).
- The order in which genes function in a biosynthetic or signaling pathway can be deduced from the phenotype of double mutants defective in two steps in the affected process.
- Functionally significant interactions between proteins can be deduced from the phenotypic effects of allele-specific suppressor mutations or synthetic lethal mutations.
- By evaluating combinations of double mutants for all of the genes in an organism, it is possible to construct a global map of the network of functional gene interactions within a cell. Such a map has been constructed for the 6000 genes of *S. cerevisiae*, and it should be possible to construct an equivalent map of the 20,000 mammalian genes.

6.2 DNA Cloning and Characterization

Detailed studies of the structure and function of a gene at the molecular level require large quantities of the individual gene in pure form. Researchers use **DNA cloning** as a way to prepare large numbers of identical DNA molecules. DNA cloning uses a variety of techniques, often referred to as *recombinant DNA technology*. **Recombinant DNA** is simply any DNA molecule composed of sequences derived from different organisms.

The key to cloning a DNA fragment of interest is to link it into a **vector** DNA molecule that can replicate within a host cell. Such a vector could be a bacterial plasmid or a modified viral genome, for example. The DNA fragment is inserted into the vector, forming a single recombinant DNA molecule. That recombinant molecule is introduced into a host cell, and the inserted DNA is replicated along with the vector, generating a large number of identical DNA molecules. The basic scheme can be summarized as follows:

$$\begin{array}{c}\text{Vector} + \text{DNA fragment}\\ \downarrow \\ \text{Recombinant DNA}\\ \downarrow \\ \text{Replication of recombinant DNA within host cells}\\ \downarrow \\ \text{Isolation, sequencing, and manipulation}\\ \text{of purified DNA fragment}\end{array}$$

Although investigators have devised numerous experimental variations, this flow diagram indicates the essential steps in DNA cloning.

In this section, we first describe methods for isolating a specific sequence of DNA from a sea of other DNA sequences. This process often involves cutting the genome into fragments and then placing each fragment in a vector so that the entire collection can be propagated as recombinant molecules in separate host cells. While many different types of vectors exist, our discussion will mainly focus on plasmid vectors in *Escherichia coli* host cells, which are commonly used. Various techniques can then be employed to identify the sequence of interest from this collection of DNA fragments. Once a specific DNA fragment is isolated, the exact sequence of nucleotides in the fragment can be determined. We end with a discussion of the polymerase chain reaction (PCR). This powerful and versatile technique can be used in many ways to

generate large quantities of a specific sequence and to manipulate DNA in the laboratory. The various uses of cloned DNA fragments are discussed in subsequent sections.

Restriction Enzymes and DNA Ligases Allow Insertion of DNA Fragments into Cloning Vectors

A major objective of DNA cloning is to obtain discrete, small regions of an organism's DNA that constitute specific genes. In addition, only relatively small DNA molecules can be inserted into any of the available vectors. For these reasons, the very long DNA molecules that compose an organism's genome must be cleaved into fragments that can be inserted into the vector DNA. Two types of enzymes — restriction enzymes and DNA ligases — are used to produce such recombinant DNA molecules.

Cutting DNA Molecules into Small Fragments

Restriction enzymes are endonucleases produced by bacteria that typically recognize specific 4–8-bp sequences, called *restriction sites*, and cleave both DNA strands at these sites. Restriction sites commonly are short *palindromic* sequences; that is, the restriction-site sequence is the same on each DNA strand when read in the 5′ to 3′ direction (Figure 6-11).

FIGURE 6-11 Cleavage of DNA by the restriction enzyme *Eco*RI. This restriction enzyme from *E. coli* makes staggered cuts at the specific 6-bp palindromic sequence shown, yielding fragments with single-stranded, complementary 4-base sticky ends. Many other restriction enzymes also produce fragments with sticky ends.

For each restriction enzyme, bacteria also produce a *modification enzyme*, which protects a host bacterium's own DNA from cleavage by modifying the host DNA at or near each potential cleavage site. The modification enzyme adds a methyl group to one or two bases, usually within the restriction site. When a methyl group is present there, the restriction endonuclease is prevented from cutting the DNA. Together, the restriction endonuclease and the modification enzyme form a restriction-modification system that protects the host DNA while it destroys incoming foreign DNA (e.g.,

bacteriophage DNA or DNA taken up during transformation) by cleaving it at all the available restriction sites.

Many restriction enzymes make staggered cuts in the two DNA strands at the corresponding restriction site, generating fragments that have a single-stranded *tail* at both ends (see Figure 6-11). The tails on the fragments generated at a given restriction site are complementary to those on all other fragments generated by the same restriction enzyme. At room temperature, these *sticky ends* can transiently base-pair with those on other DNA fragments generated with the same restriction enzyme.

The DNA isolated from an individual organism has a specific sequence that, purely by chance, contains a specific set of restriction sites. Thus a given restriction enzyme will cut the DNA from a particular source into a reproducible set of fragments called *restriction fragments*. The frequency with which a restriction enzyme cuts DNA, and thus the average size of the resulting restriction fragments, depends largely on the length of the recognition site. For example, a restriction enzyme that recognizes a 4-bp site will cleave DNA an average of once every 4^4, or 256, base pairs, whereas an enzyme that recognizes an 8-bp sequence will cleave DNA an average of once every 4^8 base pairs (65 kb). Hundreds of different restriction enzymes have been identified from different species of bacteria. Thus DNA molecules can be cut at a large number of

different sequences corresponding to the recognition sites of these enzymes.

Inserting DNA Fragments into Vectors

DNA fragments with either sticky ends or blunt ends can be inserted into vector DNA with the aid of *DNA ligase*. During normal DNA replication, DNA ligase catalyzes the end-to-end joining (ligation) of short fragments of DNA. For purposes of DNA cloning, purified DNA ligase is used to covalently join together the ends of a restriction fragment with the ends of the restriction enzyme–cut vector DNA by forming the standard covalent phosphodiester bonds of DNA (Figure 6-12). DNA ligase from bacteriophage T4 can ligate complementary sticky ends as well as two blunt DNA ends. However, blunt-end ligation is inherently inefficient and requires a higher concentration of both DNA and DNA ligase than does ligation of sticky ends.

FIGURE 6-12 Ligation of restriction fragments with complementary sticky ends. In this example, vector DNA cut with *Eco*RI is mixed with a sample containing restriction fragments

produced by cleaving genomic DNA with several different restriction enzymes. The short base sequences composing the sticky ends of each fragment type are shown. The sticky end on the cut vector DNA (a') base-pairs only with the complementary sticky ends on the *Eco*RI fragment (a) in the genomic sample. The adjacent $3'$ hydroxyl and $5'$ phosphate groups (red) on the base-paired fragments are then covalently joined (ligated) by T4 DNA ligase.

Isolated DNA Fragments Can Be Cloned into *E. coli* Plasmid Vectors

Let's take a closer look at the plasmids used as vectors. **Plasmids** are circular, double-stranded DNA (dsDNA) molecules that replicate separately from a cell's chromosomal DNA. These extrachromosomal DNAs, which occur naturally in bacteria and in lower eukaryotic cells (e.g., yeast), exist in a symbiotic relationship with their host cell. Like the host-cell chromosomal DNA, plasmid DNA is duplicated before every cell division. During cell division, copies of the plasmid DNA segregate to each daughter cell, ensuring that the plasmid continues to be propagated through successive generations of the host cell.

The plasmids most commonly used in recombinant DNA technology are those that replicate in *E. coli*. Investigators have engineered these plasmids to optimize their use as vectors in DNA cloning — for instance, by removing unneeded portions from naturally occurring *E. coli* plasmids. Removal of unneeded portions yields plasmid vectors about 1.2–3 kb in length that contain three regions essential

for DNA cloning: a replication origin (ORI); a marker that permits selection of plasmids that have the incorporated gene (*selectable marker*), usually a drug-resistance gene; and a region in which exogenous DNA fragments can be inserted (Figure 6-13).

FIGURE 6-13 Basic components of a plasmid cloning vector that can replicate within an *E. coli* cell. Plasmid vectors contain a replication origin (ORI) sequence where DNA replication can be initiated by host-cell enzymes. They also contain a gene that functions as a selectable marker, such as amp^r, which encodes the enzyme β-lactamase and confers resistance to ampicillin. Inclusion of a synthetic polylinker containing the recognition sequences for several different restriction enzymes increases the versatility of a plasmid vector since the vector is designed so that each site in the polylinker is unique on the plasmid. Exogenous DNA can be inserted into the polylinker without disturbing the ability of the plasmid to replicate or express the amp^r gene.

Figure 6-14 outlines the general procedure for cloning a DNA fragment using *E. coli* plasmid vectors. When *E. coli* cells are mixed with recombinant vector DNA and subjected to a stress such as heat shock, a small fraction of the cells will take up the plasmid DNA, a process known as **transformation**. Typically, 1 cell in about 10,000 incorporates a *single* plasmid DNA molecule and thus becomes transformed. The rare transformed cells can be easily selected by use of a selectable marker. For instance, if the plasmid carries a gene that confers resistance to the antibiotic ampicillin, transformed cells can be selected by growing them in a medium containing ampicillin. All the antibiotic-resistant progeny cells that arise from the initial transformed cell will contain plasmids with the same inserted DNA. Since all the cells in a colony arise from a single transformed parent cell, they constitute a **clone** of cells, and the initial fragment of DNA inserted into the parental plasmid is referred to as *cloned DNA* or a *DNA clone*.

EXPERIMENTAL FIGURE 6-14 DNA cloning in a plasmid vector permits amplification of a DNA fragment. A fragment of DNA to be cloned is first inserted into a plasmid vector containing an ampicillin-resistance gene (amp^r), such as that shown in Figure 6-13. Only the few cells transformed by incorporation of a plasmid will survive on ampicillin-containing medium. In transformed cells, the plasmid DNA replicates and segregates into daughter cells, resulting in the formation of an ampicillin-resistant colony in which each cell contains the cloned DNA.

The versatility of an *E. coli* plasmid vector is increased by the addition of a *polylinker*, a synthetically generated sequence

containing one copy of each of several different restriction sites that are not present elsewhere in the plasmid sequence (see Figure 6-13). Typically, the polylinker is cleaved with two different restriction enzymes in preparation to accept a DNA fragment prepared with two different sticky ends formed by cleavage by the same two enzymes. Such a strategy eliminates unwanted by-products such as a cleaved plasmid vector that has reclosed and greatly increases the efficiency of cloning DNA fragments.

Plasmid cloning vectors are useful for propagating DNA fragments up to about 20 kb in length, but fragments longer than this cannot be reliably replicated within one cell-division cycle. For some purposes, such as the isolation and manipulation of large segments of the human genome, it is desirable to clone DNA segments as large as several megabases [1 megabase (Mb) = 1 million base pairs]. For this purpose, specialized plasmid vectors known as *BACs (b*acterial *a*rtificial *c*hromosomes) have been developed. One type of BAC uses a replication origin, derived from an *E. coli* plasmid, known as the *F factor*. The F factor, and cloning vectors derived from it, can be stably maintained at a single copy per *E. coli* cell even when it contains inserted sequences of up to about 2 Mb. Production of BAC libraries requires special methods for the isolation, ligation, and transformation of large segments of DNA because segments of DNA larger than about 20 kb are highly vulnerable to mechanical breakage even by standard manipulations such as pipetting.

Yeast Genomic Libraries Can Be Constructed with Shuttle Vectors and Screened by Functional Complementation

A collection of DNA molecules, each cloned into a vector molecule, is known as a **DNA library**. When genomic DNA from a particular organism is the source of the starting DNA, the set of clones that collectively represent all the DNA sequences in the genome is known as a *genomic library*. Once a genomic library is established, investigators need ways to isolate the cloned genes that are relevant to the function they are studying. For example, investigators may have identified an interesting recessive mutation in an experimental organism and would like to isolate the cloned wild-type copy of the gene from their genomic library. The method frequently used for this is referred to as **functional complementation**.

Let's look at a functional complementation assay in yeast. Yeast genes that are cloned in special *E. coli* plasmids can be introduced into mutant yeast cells to identify the wild-type gene that is defective in the mutant strain. Because genes of the yeast *Saccharomyces* do not contain multiple introns, they are sufficiently compact that an entire sequence of as many as 10 genes can be included in a genomic DNA fragment inserted into a plasmid vector.

A plasmid genomic library that is to be screened by functional complementation in yeast cells needs to be constructed so that it contains clones of all the yeast genes. The plasmid vector carrying the clones must be capable of replication in both *E. coli* cells and yeast cells: in *E. coli* cells to produce the clones and in yeast cells to screen for functional complementation. This type of vector, capable of propagation in two different hosts, is called a **shuttle vector**. The structure of a typical yeast shuttle vector is shown in Figure 6-15a. This vector contains the basic elements that permit cloning of DNA fragments in *E. coli* as well as sequences required for its propagation in yeast.

Lodish et al., Molecular Cell Biology, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 6-15 A yeast genomic library can be constructed in a plasmid shuttle vector that can replicate in yeast and in *E. coli*. (a) Components of a typical plasmid shuttle vector for cloning *Saccharomyces* genes. The presence of a yeast replication origin (ARS) and a yeast centromere (CEN) allows stable replication and segregation in yeast. Also included is a yeast selectable marker such as *URA3*, which allows a *ura3* mutant to grow on medium lacking uracil. Finally, the vector contains sequences for replication and selection in *E. coli* (ORI and amp^r) and a polylinker for easy insertion of yeast DNA fragments. (b) Typical protocol for constructing a yeast genomic library. Partial digestion of total yeast genomic DNA with *Sau*3A is adjusted to generate fragments with an average size of ~10 kb. The vector is prepared to accept the genomic fragments by digestion with *Bam*HI, which produces the same sticky ends as *Sau*3A. Each transformed clone of *E. coli* that grows after selection for ampicillin resistance contains a single type of yeast DNA fragment.

To increase the probability that all regions of the yeast genome will be successfully cloned and represented in the plasmid library, the genomic DNA is usually only partially digested to yield overlapping

restriction fragments of ~10 kb. These fragments are then ligated into a shuttle vector in which the polylinker has been cleaved with a restriction enzyme that produces sticky ends complementary to those on the yeast DNA fragments (Figure 6-15b). Because the 10-kb restriction fragments of yeast DNA are incorporated into the shuttle vectors randomly, at least 10^5 *E. coli* colonies, each containing a particular recombinant shuttle vector, are necessary to ensure that each region of yeast DNA has a high probability of being represented in the library at least once.

Figure 6-16 outlines how such a yeast genomic library can be screened to isolate the wild-type gene corresponding to one of the temperature-sensitive *cdc* mutations mentioned earlier in this chapter. The starting yeast strain is a double mutant that requires uracil for growth due to a $ura3^-$ mutation and is temperature sensitive due to a *cdc28* mutation identified by its phenotype (see Figure 6-6b). Recombinant plasmids isolated from the yeast genomic library are mixed with yeast cells under conditions that promote transformation of the cells with foreign DNA. Since transformed yeast cells carry a plasmid-borne copy of the wild-type *URA3* gene, they can be selected by their ability to grow in the absence of uracil. Typically, about 20 petri dishes, each containing about 500 yeast transformants, are sufficient to represent the entire yeast genome. This collection of yeast transformants can be maintained at 23 °C, a temperature permissive for growth of the *cdc28* mutant. The entire collection on 20 plates is then transferred to replica plates, which

are maintained at 36 °C, a nonpermissive temperature for *cdc* mutants. Yeast colonies that carry recombinant plasmids expressing a wild-type copy of the *CDC28* gene will be able to grow at 36 °C. Once temperature-resistant yeast colonies have been identified, plasmid DNA can be extracted from the cultured yeast cells and analyzed by DNA sequencing, a topic we take up shortly.

EXPERIMENTAL FIGURE 6-16 Screening of a yeast genomic library by functional complementation can identify clones carrying the normal form of a mutant yeast gene. In this example, a wild-type *CDC28* gene is isolated by complementation of a temperature-sensitive *cdc28* yeast mutant. The yeast genomic library prepared as shown in Figure 6-15 is transformed into a $ura3^-$, temperature-sensitive cdc mutant strain. The relatively few transformed yeast cells, which contain recombinant plasmid DNA, can grow in the absence of uracil at 23 °C. When these colonies are replica-plated and incubated at 36 °C (a nonpermissive temperature), only clones carrying a library plasmid that contains the wild-type copy of the *CDC* gene will survive. LiOAC = lithium acetate; PEG = polyethylene glycol.

cDNA Libraries Represent the Sequences of Protein-Coding Genes

Genomic libraries are ideal for representing the genetic content of relatively simple organisms such as bacteria or yeast, but present certain experimental difficulties for higher eukaryotes. First, the genes of eukaryotes usually contain extensive intron sequences and can therefore be too large to be inserted intact into plasmid vectors. Within a genomic library, the sequences of individual genes are often broken apart and carried in more than one clone. Moreover, the presence of introns and long intergenic regions in genomic DNA often makes it difficult to identify the important parts of a gene that actually encode protein sequences. For example, only about 1.5 percent of the human genome actually represents protein-coding gene sequences. Thus for many studies, cellular mRNAs, which lack the noncoding regions present in genomic DNA, are a more useful starting material for generating a DNA library. In this approach, DNA copies of mRNAs, called **complementary DNAs (cDNAs)**, are synthesized and cloned into plasmid vectors. A large collection of the resulting cDNA clones, representing all the mRNAs expressed in a cell type, is called a *cDNA library*.

The first step in preparing a cDNA library is to isolate the total mRNA from the cell type or tissue of interest. Because of their poly(A) tails, mRNAs are easily separated from the much more prevalent rRNAs and tRNAs present in a cell extract by use of a

matrix to which short strings of thymidylate (oligo-dTs) are linked. The crucial step for preparing cDNAs from cellular mRNAs is the synthesis of a DNA strand complementary to the mRNA. This synthesis is carried out by the enzyme *reverse transcriptase*, which is found in retroviruses, and is similar to DNA polymerase except that reverse transcriptase uses RNA as a template for synthesis of a complementary DNA strand. As with DNA polymerase, DNA synthesis by reverse transcriptase requires a DNA primer. For cDNA synthesis, oligo-dT can efficiently base-pair with the poly(A) tails of mRNAs and serve as a primer for synthesis of a complementary DNA strand (Figure 6-17). In several steps, the resulting cDNA-mRNA hybrid molecules are converted into double-stranded cDNA molecules and DNA sequences are appended onto the ends of the cDNA to enable cloning into an appropriate vector. Figure 6-17 outlines one of the many possible procedures for generating a cDNA library inserted into a plasmid vector.

FIGURE 6-17 Generation and cloning of a cDNA copy of an mRNA. A mixture of mRNAs is the starting point for preparing recombinant plasmid clones, each containing a unique cDNA. The enzyme reverse transcriptase is used to synthesize a strand of DNA

complementary to each mRNA molecule, starting from an oligo-dT primer (steps 1 and 2). The resulting cDNA-mRNA hybrid molecules are converted in several steps into double-stranded cDNA molecules corresponding to all the mRNA molecules in the original preparation (steps 3 – 5). Each double-stranded cDNA contains an oligo-dC·oligo-dG double-stranded region at one end and an oligo-dT·oligo-dA double-stranded region at the other end. Methylation of the cDNA protects it from subsequent restriction enzyme cleavage (step 6).

To prepare double-stranded cDNAs for cloning, short double-stranded DNA molecules containing the recognition site for a particular restriction enzyme (called *linkers*) are ligated to both ends of the cDNAs using DNA ligase from bacteriophage T4 (step 7). As noted earlier, this ligase can join *blunt-ended*, double-stranded DNA molecules lacking sticky ends. The resulting molecules are then treated with the restriction enzyme specific for the attached linker, generating cDNA molecules with sticky ends (step 8a). In a separate procedure, plasmid DNA is treated with the same restriction enzyme to produce the appropriate sticky ends (step 8b).

The plasmid vector and the collection of cDNAs, all containing complementary sticky ends, are then mixed and joined covalently by DNA ligase (step 9). The resulting DNA molecules are introduced into *E. coli* cells to generate individual clones; each clone carries a cDNA derived from a single mRNA.

Only expressed gene sequences are represented in cDNA libraries, and screening cDNA libraries can be a highly efficient means to identify genes of interest in large complex genomes, such as those of mammals. However, there are two technical limitations to the utility of cDNA libraries. The first is that because of the inherent instability of RNA molecules full-length mRNAs may be partially degraded before the cDNA strand is synthesized. The longer the mRNA, the more likely that some degradation will occur; for very long mRNAs it is unlikely that the cDNA will include the 5′ end of the mRNA sequence.

The second limitation is due to different genes being transcribed at very different rates. Because of this, cDNA clones corresponding to abundantly transcribed genes will be represented many times in a cDNA library, whereas cDNAs corresponding to infrequently transcribed genes will be extremely rare or not present at all. To have a reasonable chance of including clones corresponding to slowly transcribed genes, mammalian cDNA libraries must contain 10^6–10^7 individual recombinant clones.

The Polymerase Chain Reaction Amplifies a Specific DNA Sequence from a Complex Mixture

If the nucleotide sequences at the ends of a particular DNA region are known, the intervening fragment can be amplified directly by the **polymerase chain reaction (PCR)**. Here we describe the basic PCR technique and three situations in which it is used.

The PCR depends on the ability to alternately denature (melt) double-stranded DNA molecules and hybridize complementary single strands in a controlled fashion. As outlined in Figure 6-18, a typical PCR procedure begins with heat-denaturation of a DNA sample into single strands at 95 °C. Next two synthetic oligonucleotides complementary to the 3′ ends of the DNA segment of interest (the target sequence) are added in great excess to the

denatured DNA, and the temperature is lowered to 50–60 °C. These specific oligonucleotides, which are present at a very high concentration, hybridize to their complementary sequences in the DNA sample, whereas the long strands of the sample DNA remain apart because of their comparatively low concentration. The hybridized oligonucleotides then serve as primers for DNA chain synthesis in the presence of deoxynucleotides (dNTPs) and a temperature-resistant DNA polymerase such as that from *Thermus aquaticus*, a bacterium that lives in hot springs. This enzyme, called *Taq polymerase*, can remain active even after being heated to 95 °C and can extend the primers at temperatures up to 72 °C. When synthesis is complete, the whole mixture is reheated to 95 °C to denature the newly formed DNA duplexes. After the temperature is lowered again, another cycle of synthesis takes place because excess primer is still present. Repeated cycles of denaturation (heating) followed by hybridization and synthesis (cooling) quickly amplify the sequence of interest. At each cycle, the number of copies of the sequence between the primer sites is doubled; therefore, the target sequence increases exponentially — about 1-million-fold after 20 cycles — whereas all other sequences in the original DNA sample remain unamplified.

FIGURE 6-18 The polymerase chain reaction (PCR) is widely used to amplify DNA regions with known flanking sequences. To amplify a specific region of DNA, an investigator chemically synthesizes two different oligonucleotide primers complementary to sequences of approximately 18 bases flanking the region of interest (shown here as light blue and dark blue bars). The complete reaction is composed of a complex mixture of double-stranded

DNA (usually genomic DNA containing the target sequence of interest), a stoichiometric excess of both primers, the four dNTPs, and a heat-stable DNA polymerase known as *Taq* polymerase. During each PCR cycle, the reaction mixture is first heated to separate the strands and then cooled to allow the primers to bind to complementary sequences flanking the region to be amplified. *Taq* polymerase then extends each primer from its $3'$ end, generating newly synthesized strands that extend in the $3'$ direction to the $5'$ end of the template strand. During the third cycle, two double-stranded DNA molecules are generated equal in length to the sequence of the region to be amplified. In each successive cycle, the target sequence, which anneals to the primers, is duplicated, so it eventually vastly outnumbers all other DNA sequences in the reaction mixture. Successive PCR cycles can be automated by cycling the reaction at timed intervals between a high temperature for DNA melting and a lower temperature for the annealing and elongation parts of the cycle. A reaction that cycles 20 times will amplify the specific target sequence 1-million-fold.

Direct Isolation of a Specific Segment of Genomic DNA

For organisms in which all or most of the genome has been sequenced, PCR amplification starting with the total genomic DNA is often the easiest way to obtain a specific DNA region of interest for cloning. In this application of the PCR, the two oligonucleotide primers are designed to hybridize to sequences flanking the genomic region of interest and to include sequences that are recognized by specific restriction enzymes (Figure 6-19). For an oligonucleotide to be useful as a PCR primer, it must be long enough for its sequence to occur uniquely in the genome. For most purposes, this condition is satisfied by oligonucleotides containing about 20 nucleotides. Any given 20-nucleotide sequence occurs once in every $4^{20}(\sim 10^{12})$ nucleotides by chance, so it is usually possible to

identify two specific 20-nucleotide sequences flanking the target sequence that each occur only once in the genome.

EXPERIMENTAL FIGURE 6-19 A specific target sequence in genomic DNA can be amplified by PCR for use in cloning. Each primer for PCR is complementary to one end of the target sequence and includes the recognition site for a restriction enzyme that does not have a recognition site within the target region. In this example, primer 1 contains a *Bam*HI recognition sequence, whereas primer 2 contains a *Hin*dIII recognition sequence. (Note that for clarity, in any round, amplification of only one of the two strands — the one in brackets — is shown.) After amplification, the target segments are treated with appropriate restriction enzymes, generating fragments with sticky ends. These fragments can be incorporated into complementary plasmid vectors and cloned in *E. coli* by the usual procedure (see Figure 6-14).

After amplification of the target sequence for about 20 PCR cycles, the primers are cleaved with the appropriate restriction enzymes, producing fragments with sticky ends containing the target sequence. Each fragment is then ligated to a plasmid vector whose polylinker has been cleaved by the same restriction enzymes. The resulting recombinant plasmids, all carrying the identical genomic DNA segment, can then be cloned in *E. coli* cells. With certain refinements of the PCR, even DNA segments greater than 10 kb in length can be amplified and cloned in this way.

Note that this method does not require the cloning of large numbers of restriction fragments derived from genomic DNA and their subsequent screening to identify the specific fragment of interest. In effect, the PCR method inverts this traditional approach and so

avoids its most tedious aspects. The PCR method is useful for isolating gene sequences to be manipulated in a variety of useful ways described later. In addition, the PCR method can be used to isolate gene sequences from mutant organisms to determine how they differ from the wild type.

A variation on the PCR method is used to amplify a specific cDNA sequence made from cellular mRNAs. This method, known as *reverse transcriptase–PCR (RT-PCR)*, begins with the same procedure described previously for isolation of cDNA from a collection of cellular mRNAs (see Figure 6-17). Typically, an oligo-dT primer, which hybridizes to the 3′ poly(A) tail of the mRNA, is used as the primer for the first strand of cDNA synthesis by reverse transcriptase. A specific cDNA can then be isolated from this complex mixture of cDNAs by PCR amplification using two oligonucleotide primers designed to match sequences at the 5′ and 3′ ends of the corresponding mRNA. As described previously, these primers can be designed to include restriction sites that make it possible to insert the amplified cDNA into a suitable plasmid vector.

RT-PCR can be performed so that the starting amount of a particular cellular mRNA can be determined accurately. To carry out quantitative RT-PCR, the amount of double-stranded DNA sequence produced by each amplification cycle is determined as the amplification of a particular mRNA sequence proceeds. By extrapolation from these amounts, an estimate of the starting

amount of the mRNA sequence can be obtained. Such quantitative RT-PCR analyses carried out on tissues or whole organisms using primers targeted to genes of interest provide one of the most accurate means to follow changes in gene expression.

Cloned DNA Molecules Can Be Sequenced Rapidly by Methods Based on PCR

A cloned DNA fragment is only completely characterized when its nucleotide sequence is known. The technology used to determine the sequence of a DNA segment represents one of the most rapidly developing fields in molecular biology. In the 1970s, Frederick Sanger and his colleagues developed the chain-termination procedure, which served as the basis for most DNA-sequencing methods for the next 30 years. This method is based on the selective incorporation of chain-terminating dideoxynucleotides into the daughter strands synthesized from the DNA fragment to be sequenced. Daughter-strand lengths from reactions containing each one of the four possible nucleotides provide the readout. Separation of the truncated daughter strands by gel electrophoresis, which can resolve strands that differ in length by a single nucleotide, can then reveal the lengths of all strands. From these collections of strands of different lengths, the nucleotide sequence of the original DNA fragment can be established. The Sanger method has undergone

many refinements and can now be fully automated, but because each DNA fragment of a few hundred nucleotides requires a separate, individual sequencing reaction, the overall rate at which new DNA sequences can be produced by this method is limited by the total number of reactions that can be performed at one time.

A breakthrough in sequencing technology occurred when methods were devised to allow a single sequencing instrument to carry out millions of sequencing reactions simultaneously. These sequencing methods localize the millions of reactions per square centimeter in tiny clusters on the surface of a solid substratum. In 2007, when these so-called *next generation* sequencers became commercially available, the capacity for new sequence production increased enormously, and since then, because of improvements in the technology, it has been further increasing at an amazing pace — doubling every few months. In one popular sequencing method, billions of different DNA fragments to be sequenced are prepared by ligating double-stranded linkers to their ends (Figure 6-20). Next the DNA fragments are amplified by PCR using primers that match the linker sequences. This reaction differs from the standard PCR amplification shown in Figure 6-19 in that the primers used are covalently attached to a solid substratum. Thus as the PCR amplification proceeds, one end of each daughter DNA strand is covalently linked to the substratum, and at the end of the amplification about a thousand identical PCR products are linked to the surface in a tight cluster.

EXPERIMENTAL FIGURE 6-20 Generation of clusters of identical DNA fragments attached to a solid support. A large collection of DNA fragments to be sequenced is ligated to double-stranded linkers, which become attached to each end of each fragment. The DNA is then amplified by PCR using primers matching the sequences of the linkers and that are covalently attached to a solid substratum. Ten cycles of amplification yield about a

thousand identical copies of each DNA fragment localized in a small cluster and attached at both ends to the solid substratum. These reactions are optimized to produce as many as 10^9 discrete, nonoverlapping clusters that are ready to be sequenced.

These clusters can then be sequenced by using a special microscope to image fluorescently labeled deoxyribonucleotide triphosphates (dNTPs) as they are incorporated by DNA polymerase one at a time into a growing DNA chain (Figure 6-21). First, one strand is cut and washed out, leaving a single-stranded DNA template. Then sequencing is carried out on the thousand or so identical templates in each cluster, one nucleotide at a time. All four dNTPs are fluorescently labeled and added to the sequencing reaction. After they are allowed to anneal, the substratum is imaged and the color of each cluster is recorded. Next the fluorescent tag is chemically removed and a new dNTP is allowed to bind. This cycle is repeated about a hundred times, resulting in billions of hundred-nucleotide-long sequences. The entire procedure may take about one day and yield some 10^{11} bases of sequence information.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 6-21 Using fluorescently-tagged precursors for high-throughput sequence determination. (a) The reaction begins with the cleaving of one strand of the amplified, clustered DNA (see Figure 6-20). After denaturation, a single DNA strand remains attached to the substratum. A synthetic oligodeoxynucleotide is used as the primer for the polymerization reaction, which also contains dNTPs, each fluorescently tagged with a different color. The fluorescent tag is designed to block the $3'$ OH group on the dNTP so that once the fluorescent dNTP has been incorporated, further elongation is not possible. Because DNA polymerase will incorporate the same fluorescently labeled dNTP into each of the thousand or so identical DNA copies in a cluster, the entire cluster will be uniformly labeled with the same fluorescent color, which can be imaged in a special microscope. (b) Five images from the same field of view, each corresponding to an individual cycle of dNTP addition. Each colored dot represents a cluster of identical DNA fragments. After each image is made, the fluorescent tags are removed by a chemical reaction that leaves a new primer terminus available for the next cycle of dNTP addition. As can be seen for the circled colored dot, the color changes in each reaction cycle according to which nucleotide is added to the DNA fragments (from the five panels the sequence of the circled fragment would be read: A-C-C-T-T). A typical sequencing reaction may carry out a hundred cycles of NTP addition, allowing a hundred bases of sequence for each cluster to be determined. Thus a total sequencing reaction of this type may generate as much as 3×10^{11} bases of sequence information in about two days.

[Part (b) A. Loehr and A. W. Zaranek for the Harvard Personal Genome Project.]

In order to sequence a long, continuous region of genomic DNA, or even the entire genome of an organism, researchers usually employ one of the strategies outlined in Figure 6-22. The first method requires the isolation of a collection of cloned DNA fragments whose sequences overlap. Once the sequence of one of these fragments is determined, oligonucleotides based on that sequence can be chemically synthesized for use as primers in sequencing the adjacent overlapping fragments. In this way, the sequence of a long stretch of DNA is determined incrementally by sequencing of the overlapping, cloned DNA fragments that compose it. A second method, which is called *whole genome shotgun sequencing*, bypasses the time-consuming step of isolating an ordered collection of DNA segments that span the genome. This method involves simply sequencing random clones from a genomic library. A sufficient number of clones are chosen for sequencing so that on average, each segment of the genome is sequenced about 10 times. This degree of coverage ensures that each segment of the genome is sequenced more than once. The entire genomic sequence is then assembled using a computer algorithm that aligns all the segments using their regions of overlap. Whole genome shotgun sequencing is the fastest and most cost-effective method for sequencing long stretches of DNA, and most genomes, including the human genome, have been sequenced by this method.

EXPERIMENTAL FIGURE 6-22 Two strategies for assembling whole genome sequences. One method (*left*) depends on isolating and assembling a set of cloned DNA fragments that

span the genome. This can be done by matching cloned fragments by hybridization or by alignment of restriction-site maps. The DNA sequence of the ordered clones can then be assembled into a complete genomic sequence. The alternative method (*right*) depends on the relative ease of automated DNA sequencing and bypasses the laborious step of ordering a DNA library. By sequencing enough random clones from the library so that each segment of the genome is represented from 3 to 10 times, it is possible to reconstruct the genomic sequence by computer alignment of the very large number of sequence fragments.

KEY CONCEPTS OF SECTION 6.2

DNA Cloning and Characterization

- In DNA cloning, recombinant DNA molecules are formed in vitro by inserting DNA fragments into vector DNA molecules. The recombinant DNA molecules are then introduced into host cells, where they replicate, producing large numbers of recombinant DNA molecules.
- Restriction enzymes (endonucleases) typically cut DNA at specific 4–8-bp palindromic sequences, producing defined fragments that often have self-complementary, single-stranded tails (sticky ends).
- Two restriction fragments with complementary ends can be joined with DNA ligase to form a recombinant DNA molecule (see Figure 6-12).
- *E. coli* cloning vectors are small circular DNA molecules (plasmids) that include three functional regions: a replication origin, a selectable marker gene, and a site where a DNA fragment can be inserted. Transformed cells carrying a vector grow into colonies on the selection medium (see Figure 6-14).
- A genomic library is a set of clones carrying restriction fragments produced by cleavage of the entire genome.
- Shuttle vectors that can replicate in both yeast and *E. coli* can be used to construct a yeast genomic library. Specific genes can be isolated by their ability to complement the corresponding mutant genes in yeast cells (see Figure 6-16).
- In cDNA cloning, expressed mRNAs are reverse-transcribed into complementary DNAs, or cDNAs. A cDNA library is a set of cDNA clones prepared from the mRNAs isolated from a particular type of cell or tissue (see Figure 6-17).
- The polymerase chain reaction (PCR) permits exponential amplification of a specific segment of DNA from a single initial template DNA molecule if the sequence flanking the DNA region to be amplified is known (see Figure 6-19).

- PCR is a highly versatile method that can be programmed to amplify a specific genomic DNA sequence, a cDNA, or a sequence at the junction between a DNA transposon and flanking chromosomal sequences.
- DNA fragments up to about 100 nucleotides long can be sequenced by generating clusters of identical fragments by PCR and imaging fluorescently labeled nucleotide precursors incorporated by DNA polymerase (see Figures 6-20 and 6-21).
- Whole genome sequences can be assembled from the sequences of a large number of overlapping clones from a genomic library (see Figure 6-22).

6.3 Using Sequence Information to Identify Genes and Deduce Their Function

By using automated DNA-sequencing techniques and computer algorithms to piece together sequence data, researchers have determined vast amounts of DNA sequence, including nearly the entire genomic sequence of humans and of many experimental organisms. By now, the genomic sequences have been completely determined for all of the major model organisms and thousands of viruses, bacteria, archea, and eukaryotes including representatives of all of the 35 or so metazoan phyla.

The genome sequence of an organism contains the information that specifies the sequence of all of its protein and RNA components. In addition, regulatory sequences in the genome specify when and where each of these proteins or RNA molecules is expressed. Thus it should be possible, at least in principle, to learn almost all there is to know about an organism — what it is, how it functions, and how it evolved — from a properly informed reading of its genomic sequence. Useful biological information is extracted from sequence data, largely by computers that search for meaningful patterns in sequence data by comparing one sequence to another. The effort to extract biological information from genomes has led to the

emergence of an enormously powerful new field of biology: *bioinformatics*.

Although this field depends upon the highly technical application of advanced computer algorithms, the fundamental principle underlying all of bioinformatics is not complicated. Bioinformatic reasoning is based on the understanding that life on earth arose only once and all genome sequences, either existing or extinct, are derived from this single common ancestor through a continual process of random mutation and natural selection. Thus, any substantial similarity between two sequences from different species can be attributed to one of two causes. Either the organisms are closely related such that not enough time has passed for random differences to have accumulated by mutation, or the sequence is constrained to perform some important function and so mutational variations have been systematically weeded out by natural selection. This latter case is known as **conservation**, and we would say that a sequence is conserved if it has remained substantially unchanged in organisms that are evolutionarily so far apart that most sequences have lost recognizable similarity due to random mutations. Most bioinformatics reasoning rests on the following overarching concept: *the more a sequence shows conservation among distantly related organisms, the more important its function is likely to be*.

In this section, we first show how protein coding genes are identified in genomic sequences. Next we examine how functional

and evolutionary relationships between proteins are studied. Finally, we explore the relationship between the complexity of an organism and the number of protein-coding genes that it contains.

Most Genes Can Be Readily Identified Within Genomic DNA Sequences

The complete genomic sequence of an organism contains within it the information needed to deduce the sequence of every protein made by the cells of that organism. Different strategies are used to deduce protein sequences for prokaryotes and eukaryotes. In the genomes of prokaryotes, the protein-coding sequences are continuous reading frames that are not broken up by introns. Thus for prokaryotes the vast majority of protein-coding sequences can be found simply by scanning the genomic sequence for **open reading frames (ORFs)** of significant length. An ORF is defined as a continuous sequence of triplet codons that does not contain a stop codon.

ORFs that are never translated into amino acids may appear by random chance. How many codons must an ORF contain for us to be sure that it is part of a gene? This number can be calculated by utilizing the probability that a run of non-stop codons has occurred by chance. The probability of a non-stop codon in a random sequence is 61/64, which is simply the fraction of the 64 possible

triplet codons that are not stop codons. Thus the probability of a random sequence containing an ORF of greater than n codons is $(61/64)^n$, which is the joint probability of *not* encountering a stop codon n times in a row. Taking the average length of a prokaryotic protein to be about 300 amino acids, the calculated probability of an ORF greater than this length *arising by chance* is only 5.6×10^{-7}, and it is unlikely that even one ORF of this length would occur in an entire bacterial genomic sequence of 4×10^6 base pairs. In practice, prokaryotic genes can be reliably found by simply searching for ORFs greater than about 100 codons.

ORF analysis correctly identifies more than 90 percent of the genes in bacteria and in eukaryotes such as *S. cerevisiae* that have few introns. Some of the very shortest genes, however, are missed by this method, and occasionally long open reading frames that are not actually genes do arise by chance. Both types of misassignments can be corrected by more sophisticated analysis of the sequence and by genetic tests for gene function. Of the genes identified in this manner, about half were already known by some functional criterion such as mutant phenotype. Some of the proteins encoded by the remaining putative genes identified by ORF analysis have been assigned functions based on their sequence similarity to known proteins in other organisms.

More sophisticated algorithms are required to identify genes in organisms with a more complex genome structure. Scanning for

ORFs is a poor method for finding genes in higher eukaryotes because the coding sequences of most genes are broken up by multiple noncoding introns (humans have an average of 9 introns per gene), and the relatively short ORFs derived from exons are not easily distinguished from the many short ORFs that arise in the genome by chance. In a typical gene-sized segment of genomic DNA, more than a thousand fortuitous ORFs greater in length than the average exon would be expected. A much more reliable way to find eukaryotic genes is to consider the possible encoded amino acid sequences, not just the presence of an ORF. One way to do this is to have a computer generate a list of all of the thousands of peptide sequences produced by hypothetical translation of all ORFs of any length with a specific genome sequence. Each of these peptide sequences would then be compared to the entire database of protein sequences to look for significant matches to a known protein family. Finding multiple short ORFs from the same region of DNA that show similarity to sequential segments of a single known protein would provide strong evidence that the set of ORFs is the set of exons for a single human gene.

The best gene-finding algorithms combine all the available data that might suggest the presence of a gene at a particular genomic site. Relevant data include alignment of the sequence under examination to a full-length cDNA sequence; alignment to a partial cDNA sequence, generally 200–400 bp in length, known as an *expressed sequence tag (EST)*; fitting to models for exon, intron, and splice-site

sequences; and similarity to gene sequences from other organisms. Using these computer-based bioinformatic methods, computational biologists have identified approximately 21,000 protein-coding genes in the human genome.

A particularly powerful method for identifying human genes is to compare the human genomic sequence with that of other mammals, particularly the mouse. Humans and mice are sufficiently related to have most genes in common, although largely nonfunctional DNA sequences, such as introns and the regions between genes, tend to be very different because these sequences are not under strong selective pressure. In addition to conserved coding sequences of exons, the segments of the human and mouse genome that are important for gene structure and function, such as intron splice sites or transcription-control regions, can be identified because these sequences tend to be conserved.

Bioinformatic Principles Can Be Used to Deduce the Likely Functional Consequences of Mutations

Once a gene has been identified, comparison of a mutant gene sequence with that of wild type can be used to deduce the likely effect of the mutation on the gene product. Mutations that alter the coding sequence of a gene usually provide the most insight into

function of the expressed protein. The most severe types of mutations introduce a premature stop codon (*nonsense* mutations) or change the reading frame of a gene by the addition or deletion of bases (*frameshift* mutations). Nonsense mutations and frameshift mutations almost always cause a complete loss of gene function and are therefore often referred to as *null alleles. Point mutations* that result in substitution of one amino acid for another (*missense* mutations) can have dramatic effects on gene function or they can have no effect at all, and the principle of conservation of the functionally important parts of a gene can contribute to an educated guess as to the severity of the effect of a missense mutation. For example, a missense mutation that changed a highly conserved amino acid residue to a chemically dissimilar residue would likely have a large effect on protein function, whereas a change in a non-conserved position would likely have a mild effect or no effect at all. A point mutation that changes a codon to a different codon that codes for the same amino acid will almost never have an effect on gene function and is therefore considered to be a *silent* mutation.

In higher eukaryotes, point mutations outside the coding sequence of genes rarely have dramatic effects on phenotype. This is not because promoter sequences and sequences at splice sites are not important for gene function, but rather that the function of these cis-acting sequences is usually distributed redundantly among multiple nucleotide residues such that no single point mutation will have a large effect. The majority of point mutations outside gene-

coding sequences that have observable effects on gene function interfere with pre-mRNA splicing, and these mutations often lie in highly conserved residues that are pivotal to selecting the proper pre-mRNA splice site.

The Function and Evolutionary Origins of Genes and Proteins Can Be Deduced from Their Sequence

As discussed in Chapter 3, proteins with similar functions often contain similar amino acid sequences that correspond to important functional domains in the three-dimensional structure of the proteins. By comparing the amino acid sequence of the protein encoded by a newly cloned gene with the sequences of proteins of known function, an investigator can look for sequence similarities that provide clues to the function of the encoded protein. Because of the degeneracy in the genetic code, related proteins invariably exhibit much more sequence conservation than the genes encoding them. For this reason, protein sequences, rather than the corresponding DNA sequences, are usually compared.

The most widely used computer program for this purpose is known as BLAST (*b*asic *l*ocal *a*lignment *s*earch *t*ool). The BLAST algorithm divides the protein sequence to be examined (known as the *query sequence*) into shorter segments and then searches the database for

significant matches to any of the stored sequences. The matching program assigns a high score to identically matched amino acids and a lower score to matches between amino acids that are related (e.g., hydrophobic, polar, positively charged, negatively charged) but not identical. When a significant match is found for a segment, the BLAST algorithm searches locally to extend the region of similarity. After searching is completed, the program ranks the matches between the query protein and various known proteins according to their *p-values*. This parameter is a measure of the probability of finding such a degree of similarity between two protein sequences by chance. The lower the *p*-value, the greater the sequence similarity between two sequences. A *p*-value less than about 10^{-3} is usually considered significant evidence that two proteins share a common ancestor. Many alternative computer programs have been developed that can detect relationships between proteins that are more distantly related to each other than can be detected by BLAST. The development of such methods is currently an active area of bioinformatics research.

To illustrate the power of this sequence-comparison approach, let's consider the human gene *NF1*. Mutations in *NF1* are associated with the inherited disease neurofibromatosis 1, in which multiple tumors develop in the peripheral nervous system, causing large protuberances in the skin. After a cDNA clone of *NF1* was isolated and sequenced, the deduced sequence of the NF1 protein was checked against all other protein sequences in GenBank. A region of

NF1 protein was discovered to have considerable homology to a portion of the yeast protein called *Ira* (Figure 6-23). Previous studies had shown that Ira is a GTPase-activating protein (GAP) that modulates the GTPase activity of the monomeric G protein called *Ras* (see Figure 3-35). Its homology with Ira suggested that NF1 also regulated Ras activity. As we examine in detail in Chapter 16, GAP and Ras proteins normally function to control cell replication and differentiation in response to signals from neighboring cells. Functional studies on the normal NF1 protein, obtained by expression of the cloned wild-type gene, showed that it did indeed regulate Ras activity. These findings suggest that patients with neurofibromatosis express a mutant NF1 protein in cells of the peripheral nervous system, leading to abnormally high signaling through Ras protein. The enhanced rate of signaling in turn leads to excessive cell division and formation of the tumors characteristic of the disease.

FIGURE 6-23 Comparison of the regions of human NF1 protein and *S. cerevisiae* Ira protein that show significant sequence similarity. The NF1 and the Ira sequences are shown on the top and bottom lines of each row, respectively, in the one-letter amino acid code (see Figure 2-14). Amino acids that are identical in the two proteins are highlighted in dark blue. Amino acids with chemically similar but nonidentical side chains are highlighted in light blue. Black dots indicate gaps in the upper and lower protein sequences, inserted by the algorithm in order to maximize the alignment of homologous amino acids. The BLAST *p*-value for these two sequences is 10^{-28}, indicating a high degree of similarity.

[Data from G. Xu et al., 1990, *Cell* **62**:599.]

Even when the BLAST algorithm finds no significant overall similarities, a query sequence may nevertheless share a short sequence with known proteins that is functionally important. Such short segments, referred to as **structural motifs**, recur in many different proteins. These recurring segments generally have similar functions. Several such motifs are described in Chapter 3 and illustrated in Figure 3-7. To search for these and other motifs in a new protein, researchers compare the query protein sequence with a database of known motif sequences.

Comparison of Related Sequences from Different Species Can Give Clues to Evolutionary Relationships Among Proteins

BLAST searches for related protein sequences may reveal that proteins belong to a protein family shared among related organisms. Consider, for example, the *tubulin* proteins, the basic subunits of microtubules, which are important components of the cytoskeleton (see Chapter 18). According to the simplified scheme in Figure 6-24a, the earliest eukaryotic cells are thought to have contained a single tubulin gene that was duplicated early in evolution. The two copies of the original tubulin gene subsequently diverged in sequence and became the ancestral versions of the α- and β-tubulin genes. As different species diverged from these early eukaryotic cells, each of these gene sequences further diverged, giving rise to the slightly different forms of α-tubulin and β-tubulin now found in each species.

FIGURE 6-24 Generation of diverse tubulin sequences during the evolution of eukaryotes. (a) Probable mechanism giving rise to the tubulin genes found in existing species. It is possible to deduce that a gene-duplication event occurred before speciation because the α-tubulin sequences from different species (e.g., humans and yeast) are more alike than are the α-tubulin and β-tubulin sequences within a species. (b) A phylogenetic tree representing the relationship between the tubulin sequences. The branch points (nodes), indicated by

small numbers, represent common ancestral genes at the time that two sequences diverged. For example, node 1 represents the duplication event that gave rise to the α-tubulin and β-tubulin families, and node 2 represents the divergence of yeast from multicellular species. Braces and arrows indicate, respectively, the orthologous tubulin genes, which differ as a result of speciation, and the paralogous genes, which differ as a result of gene duplication. This diagram is simplified somewhat because flies, worms, and humans actually contain multiple α-tubulin and β-tubulin genes that arose from later gene duplication events.

All the different members of the tubulin family of genes (and proteins) are sufficiently similar in sequence to suggest that they arose from a common ancestral sequence. Thus all these sequences are considered to be *homologous*. More specifically, sequences that presumably diverged as a result of gene duplication (e.g., the α- and β-tubulin sequences) are described as *paralogous*. Sequences that arose because of speciation (e.g., the α-tubulin genes in different species) are described as *orthologous*. From the degree of sequence relatedness of the tubulins present in different organisms today, evolutionary relationships can be deduced, as illustrated in Figure 6-24b. Of the three types of sequence relationships, orthologous sequences are the most likely to share the same function.

Biological Complexity of an Organism Is Not Directly Related to the Number of Protein-Coding Genes in the Genome

The combination of genomic sequencing and gene-finding computer algorithms has yielded the complete inventory of protein-coding genes for a variety of organisms. Figure 6-25 shows the total number of protein-coding genes in several eukaryotic genomes that have been completely sequenced. The functions of about half the proteins encoded in these genomes are known or have been predicted on the basis of sequence comparisons. One of the surprising features of this comparison is that the number of protein-coding genes within different organisms does not seem proportional to our intuitive sense of their biological complexity. For example, the roundworm *C. elegans* apparently has more genes than the fruit fly *Drosophila*, which has a much more complex body plan and more complex behavior. And humans have only about 5 percent more protein-coding genes than *C. elegans*. When it first became apparent that humans appeared to have only a slightly more comlex genome than the simple roundworm, it was difficult to understand how such a small increase in the number of proteins could generate such a staggering difference in complexity.

FIGURE 6-25 Comparison of the number and types of proteins encoded in the genomes of different eukaryotes. For each organism, the area of the entire pie chart represents the total number of protein-coding genes, all shown at roughly the same scale. In most cases, the

functions of the proteins encoded by about half the genes are still unknown (light blue). The functions of the remainder are known or have been predicted by sequence similarity to genes of known function.

[Data from ENCODE Project Consortium, 2012, *Nature* **489**:57; J. D. Hollister, 2014, *Chromosome Res.* **22**:103; L. W. Hillier et al., 2005, *Genome Res.* **15**:1651; FlyBase: FB2015_02 Release Notes, http://flybase.org/static_pages/docs/release_notes.html; Saccharomyces Genome Data Base 2015, http://www.yeastgenome.org/genomesnapshot.]

Clearly simple quantitative differences in the number of protein-coding genes in the genomes of different organisms are inadequate for explaining differences in biological complexity. However, several phenomena can generate more complexity in the expressed proteins of higher eukaryotes than is predicted from their genomes. First, a particular gene can yield multiple functional mRNAs, and therefore multiple proteins, through alternative splicing of a pre-mRNA (see Chapter 9). In humans, the mean number of alternatively spliced mRNAs expressed per gene is about six. Second, variations in the post-translational modification of many proteins may produce functional differences. Finally, stable modifications to chromatin structure that are not evident in gene sequences can have large effects on gene expression in particular cell types (see Chapter 9). These so-called epigenetic effects can greatly contribute to biological complexity. Evolution of the increasing biological complexity of multicellular organisms probably required increasingly complex regulation of cell replication and temporal and spatial regulation of gene expression

in the cells that make up the organisms, leading to increasing complexity of embryological development.

Researchers still have not determined the specific functions of many genes and proteins identified by analysis of genomic sequences. As they unravel the functions of individual proteins in different organisms and further detail their interactions with other proteins, the resulting advances will become immediately applicable to all homologous proteins in other organisms. No doubt, when the function of every protein is known, a more sophisticated understanding of the molecular basis of complex biological systems will emerge.

KEY CONCEPTS OF SECTION 6.3

Using Sequence Information to Identify Genes and Deduce Their Function

- All species are derived from a common ancestor and have evolved by random mutation and natural selection. Sequence patterns that are conserved among distantly related species are likely to be functionally important and to have been maintained by natural selection.
- A fundamental principle of bioinformatics is that the more highly conserved a sequence is, the more important its function is likely to be.
- For organisms such as bacteria and yeast whose genes are not interrupted by introns, protein-coding genes can be identified by computer searching of the entire bacterial and yeast genomic sequences for open reading frames (ORFs).
- For most higher eukaryotes, which have relatively short coding exons separated by introns, methods other than ORF identification are required to reliably identify genes. These methods include reconstructing spliced genes from cDNA sequences, searching for similarities between hypothetical translation of ORFs and known protein sequences, and identifying conserved gene features such as intron-splice sites.

- The function of a protein that has not been isolated can often be predicted on the basis of similarity of its amino acid sequence (the query sequence) to the sequences of proteins of known function.
- A computer algorithm known as BLAST rapidly searches databases of known protein sequences to find those with significant similarity to a query protein.
- Proteins with common functional motifs, which can often be quite short, may not be identified in a typical BLAST search. Such short sequences may be located by searches of structural motif databases.
- A protein family comprises multiple proteins all derived from the same ancestral protein. The genes encoding these proteins, which constitute the corresponding gene family, arose by an initial gene-duplication event and subsequent divergence during speciation (see Figure 6-24).
- Related genes and their encoded proteins expressed in one organism that derive from a gene duplication event are paralogous, such as the α- and β-tubulin proteins that combine to form an αβ dimer building block of the microtubule. Those that derive from mutations that accumulated during speciation are orthologous. Proteins that are orthologous usually have the same function in different organisms.
- Analysis of the complete genomic sequences of several different organisms indicates that biological complexity is not directly related to the number of protein-coding genes (see Figure 6-25).

6.4 Locating and Identifying Genes That Specify Human Traits

The function of human proteins and human genes is of primary interest to cell biologists. In many cases, cell biologists will study human genes that are orthologs of genes of known cell biological function that have been studied in model organisms because these orthologs are often genes with important cell biological functions in humans as well. However, in certain key cases human genes with important functions that were not identified in model organisms have been identified solely because mutations in these genes have an observable effect on human biology. Many of these genes have been identified because they cause, contribute to, or protect against human disease.

Table 6-1 lists several of the most commonly occurring inherited diseases. Although a "disease" gene may result from a new mutation that arose in the preceding generation, most cases of inherited diseases are caused by preexisting mutant alleles that have been passed from one generation to the next for many generations.

TABLE 6-1 • Common Inherited Human Diseases

Disease	Molecular and Cellular Defect	Incidence
Autosomal Recessive		
Sickle-cell disease	Abnormal hemoglobin causes deformation of	1/625 of

	red blood cells, which can become lodged in capillaries; also confers resistance to malaria.	sub-Saharan African origin
Cystic fibrosis	Defective chloride channel (CFTR) in epithelial cells leads to excessive mucus in lungs.	1/2500 of European origin
Phenylketonuria (PKU)	Defective enzyme in phenylalanine metabolism (tyrosine hydroxylase) results in excess phenylalanine leading to mental retardation, unless restricted by diet.	1/10,000 of European origin
Tay-Sachs disease	Defective hexosaminidase enzyme leads to accumulation of excess sphingolipids in the lysosomes of neurons, impairing neural development.	1/1000 Ashkenazi Jews
Autosomal Dominant		
Huntington's disease	Defective neural protein (huntingtin) may assemble into aggregates, causing damage to neural tissue.	1/10,000 of European origin
Hypercholesterolemia	Defective LDL receptor leads to excessive cholesterol in blood and early heart attacks.	1/250 French Canadians
X-Linked Recessive		
Duchenne muscular dystrophy (DMD)	Defective cytoskeletal protein (dystrophin) leads to impaired muscle function.	1/3500 males
Hemophilia A	Defective blood clotting factor VIII leads to uncontrolled bleeding.	1/5000 males

The typical first step in deciphering the underlying cause of any inherited human disease is to identify the affected gene and its encoded protein. Historically, researchers have used whatever phenotypic clues might be relevant to make guesses about the molecular basis of inherited diseases. An early example of successful guesswork was the hypothesis that sickle-cell disease, known to be a disease of blood cells, might be caused by defective hemoglobin. This idea led to the identification of a specific amino acid substitution in hemoglobin that causes the defective hemoglobin molecules to polymerize. These polymers in turn cause the sickle-like deformation of red blood cells in individuals who have inherited two copies of the Hb^s allele for sickle-cell hemoglobin.

Most often, however, the genes responsible for inherited diseases must be found without any prior knowledge or reasonable hypotheses about the identity of the affected gene or its encoded protein. In this section, we see how human geneticists can find the gene responsible for an inherited disease by following the segregation of the disease in families. That is, geneticists trace which family members had the disease and which did not over the course of a few generations. They then look for genetic markers present in the DNA sequence that appear only in the family members with the disease. In other words, the segregation of the disease within the family can be correlated with the segregation of

many other genetic markers. The location of the genetic markers, already known, eventually leads to identification of the chromosomal position of the affected gene. Using this information, along with knowledge of the sequence of the human genome, geneticists can ultimately pinpoint the affected gene and the disease-causing mutations.

Monogenic Diseases Show One of Three Patterns of Inheritance

We have already seen that one of the most useful aspects of genetic analysis in model organisms is that the phenotype of a mutation along with knowledge of whether the mutation is genetically recessive or dominant enables biologists to deduce the function of the normal protein. Of course in humans the same types of test crosses that are used to determine dominance or recessiveness in model organisms cannot be applied. Nevertheless, researchers can determine whether a human trait is dominant or recessive by examining the pattern of inheritance of a trait in families or human populations. Thus determining the mode of inheritance along with identifying the gene or genes that are affected are the primary objectives of human genetic studies.

Human genetic diseases that result from mutation in one specific gene, referred to as *monogenic diseases*, display different inheritance

patterns depending on whether the alleles that cause them are dominant or recessive and whether they are located on an autosome or a sex chromosome. One characteristic pattern is that exhibited by a dominant allele in an autosome (i.e., one of the 22 human chromosomes that is not a sex chromosome). Because an *autosomal dominant* allele is expressed in the heterozygote, usually at least one of the parents of an affected individual will also have the disease. For example, in Huntington's disease, which is autosomal dominant, if either parent carries a mutant *HD* allele, each of his or her children (regardless of sex) has a 50 percent chance of inheriting the mutant allele and being affected (Figure 6-27a).

What are the molecular mechanisms underlying dominance? Huntington's disease, a neural degenerative disease, is caused by an expansion of the number of triplet CAG repeats in the coding sequence of a neuronal protein HTT. The mutant HTT protein that has an expanded number of glutamine residues has been shown to form protein aggregates. The fact that the mutant *HD* allele is inherited in a dominant fashion strongly implies that the symptoms of Huntington's disease result from a *gain* in propensity of the mutant HTT protein to form aggregates and not because of a *loss* of the normal HTT protein function. Diseases such as Huntington's disease caused by dominant alleles often strike in middle to late life, after reproductive age. If this were not the case, natural selection would have eliminated these alleles during human evolution.

A recessive allele in an autosome exhibits quite a different segregation pattern. Both parents must be heterozygous *carriers* of an autosomal recessive allele in order for their children to be at risk of the disease. Each child of heterozygous parents has a 25 percent chance of receiving both recessive alleles and thus being affected; a 50 percent chance of receiving one normal and one mutant allele and thus being a carrier; and a 25 percent chance of receiving two normal alleles. Related individuals (e.g., first or second cousins) have a relatively high probability of being carriers for the same recessive alleles. Thus children born to related parents are much more likely than those born to unrelated parents to be homozygous for, and therefore affected by, a rare autosomal recessive disorder.

A clear example of an autosomal recessive disease is cystic fibrosis, which results from a defective chloride-channel gene known as *CFTR* (Figure 6-26b). The presence of this defect disturbs the balance of ions across the epithelial cell layers of the lungs and intestine. Because cystic fibrosis is a recessive disease, we may deduce that the effects of the disease are due to insufficient activity of the chloride channels in the epithelial cells.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 6-26 Three common inheritance patterns for human monogenic diseases. Wild-type autosomes (A) and sex chromosomes (X and Y) are indicated by superscript plus signs. (a) In an autosomal dominant disorder such as Huntington's disease, only one mutant allele is needed to confer the disease. If either parent is heterozygous for the mutant *HD* allele, his or her children have a 50 percent chance of inheriting the mutant allele and getting the disease. (b) In an autosomal recessive disorder such as cystic fibrosis, two mutant alleles must be present to confer the disease. Both parents must be heterozygous carriers of the mutant *CFTR* allele for their children to be at risk of being affected or being carriers. (c) An X-linked recessive disease such as Duchenne muscular dystrophy is caused by a recessive mutation on the X chromosome and exhibits the typical sex-linked segregation pattern. Males born to mothers heterozygous for a mutant *DMD* allele have a 50 percent chance of

inheriting the mutant allele and being affected. Females born to heterozygous mothers have a 50 percent chance of being carriers.

The third common pattern of inheritance is that of an *X-linked recessive* allele. A recessive allele on the X chromosome will most often be expressed in males, who receive only one X chromosome from their mother, but not in females, who receive an X chromosome from both their mother and their father. The presence of an X-linked recessive allele leads to a distinctive sex-linked segregation pattern in which the disease is exhibited much more frequently in males than in females. For example, Duchenne muscular dystrophy (DMD), a muscle degenerative disease that specifically affects males, is caused by a recessive allele on the X chromosome. DMD exhibits the typical sex-linked segregation pattern in which mothers who are heterozygous, and therefore phenotypically normal, can act as carriers, transmitting the DMD allele, and therefore the disease, to 50 percent of their male progeny (Figure 6-26c).

DNA Polymorphisms Are Used as Markers for Linkage Mapping of Human Mutations

Once the mode of inheritance has been determined, the next step in finding a disease allele is to map its position with respect to known

genetic markers. Genetic mapping studies rely on exchanges of genetic information that occur during meiosis. As shown in Figure 6-27a, genetic **recombination** takes place in germ cells after the chromosomes of each homologous pair have replicated, but before the first meiotic cell division. At this time, homologous DNA sequences on maternally and paternally derived chromatids can be exchanged with each other in a process known as crossing over.

FIGURE 6-27 Recombination during meiosis can be used to map the positions of genes. (a) Consider the gametes produced by an individual that carries on one chromosome a dominant disease allele, designated *D* and linked SNP marker allele *m1,* and on the homologous chromosome the corresponding wild-type allele designated + and SNP marker *m2*. Because this arrangement of alleles is the same as in the parent of the individual these are known as parental types. If crossing over occurs within an interval between *the disease gene and the SNP marker*, then two *recombinant types* of gametes can be produced; one carries *D* and *m2* and one carries + and *m1*. The closer the SNP marker is to the disease gene, the less likely that a recombination event between them will occur, and the rarer recombinant types will be. If the markers were on different chromosomes or far apart on the same chromosome they would segregate independently of one another and recombinant types would occur with equal frequency as parental types. Note that in meiosis of the

human female, only one gamete is produced to form an egg cell. (b) Genetic mapping in humans involves scoring the genotypes of parents and offspring to determine the fraction of gametes that are recombinant types. For a cross to be informative, at least one of the parents must be heterozygous for both markers. In the example shown, the presence of the D allele in the gamete can be deduced from whether the child has the dominant trait and the presence of the m2 allele can be determined from the SNP genotype of the child. By scoring the gametes from many families in this way the genetic distance can be obtained by the fraction of recombinant types. By convention, the unit of genetic distance is a centimorgan (cM), defined as the distance between two positions along a chromosome that results in 1 recombinant individual in 100 progeny. Positions that show about as many recombinant types as parental types are said to be unlinked.

To see how genetic recombination during meiosis can be used as the basis of mapping the distances between genes, consider an individual with two different mutations, one inherited from each parent, that are located close to each other on the same chromosome. That individual can produce two different types of gametes according to whether a crossover occurs between the mutations during meiosis. If no crossover occurs between them, gametes known as *parental types*, which contain either one or the other mutation, will be produced. In contrast, if a crossover occurs between the two mutations, gametes known as *recombinant types* will be produced. In this example, recombinant chromosomes would contain either both mutations or neither one of them. Recombination events occur more or less at random along the length of chromosomes; thus the closer together two genes are, the less likely that recombination will happen to occur between them during meiosis. Thus *the less frequently recombination is observed to*

occur between two genes on the same chromosome, the closer together they must be. Two genes that are on the same chromosome and that are sufficiently close together that significantly fewer recombinant gametes than parental gametes are produced are considered to exhibit genetic **linkage**. If the number of recombinant gametes produced is not significantly less than the number of parental gametes, the two loci under consideration are considered to be *unlinked* and could be far apart on the same chromosome, or they could be on different chromosomes.

We have seen that by setting up the appropriate crosses, genetic recombination can be used in many different kinds of model organisms to determine the distance between two genetic markers that lie on the same chromosome. To find the map position of a new mutation, a process known as genetic mapping, it is necessary to carry out multiple pair-wise crosses with genetic markers of known position that span the entire genome. In the experimental organisms commonly used in genetic studies, numerous markers with easily detectable phenotypes are available for genetic mapping of mutations. For humans, there are not nearly enough phenotypic markers to carry out genetic mapping studies. Instead, recombinant DNA technology has made available a wealth of useful DNA-based molecular markers. Because most of the human genome does not encode proteins, a large amount of phenotypically inconsequential sequence variation exists between individuals. Indeed, it has been estimated that nucleotide differences between unrelated individuals

occur on an average of 1 of every 10^3 nucleotides. Since variations in DNA sequence, referred to as *DNA polymorphisms*, can be followed from one generation to the next by sequencing the DNA of individuals, they can serve as ideal genetic markers for linkage studies. Currently, a panel of as many as 10^6 different known polymorphisms whose locations have been mapped in the human genome is used for genetic linkage studies in humans.

Single-nucleotide polymorphisms (SNPs) constitute the most abundant type of DNA polymorphism and are therefore useful for constructing genetic maps of maximum resolution. Another useful type of DNA polymorphism consists of a variable number of repetitions of a two-, three-, or four-base sequence. Such polymorphisms, known as *short tandem repeats (STRs)* or *microsatellites*, presumably are formed by recombination or by slippage of either the template or newly synthesized strand during DNA replication. A useful property of STRs is that different individuals often have different numbers of repeats. The existence of multiple versions of an STR makes it more likely to produce an informative segregation pattern in a given pedigree and therefore to be of more general use in mapping the positions of disease genes. These polymorphisms can be detected by PCR amplification and DNA sequencing.

Human Linkage Studies Can Map Disease Genes with a Resolution of About 1 Mbp

Without going into all the technical considerations, let's see how a geneticist might map the allele conferring a particular dominant disease trait (e.g., familial hypercholesterolemia). The first step is to obtain DNA samples from all the members of a family containing individuals that exhibit the disease. The DNA from each individual, affected and unaffected, is then analyzed to determine that individual's genotype for a large number of known DNA polymorphisms (either STR or SNP markers can be used). The segregation pattern of each DNA polymorphism within the family is then compared with the segregation pattern of the disease under study. Polymorphisms that are not linked to the disease allele will not show any significant tendency to appear more frequently in individuals with the disease, whereas polymorphisms that are closely linked to it will almost always be present in individuals with the disease, because recombination events that would separate the disease allele and the polymorphism will be rare. Computer analysis of the segregation data is used to calculate the likelihood of linkage between each DNA polymorphism and the disease-causing allele. Under ideal circumstances, the segregation patterns from at least 10 individuals in a family are needed to establish statistically significant evidence for linkage.

In practice, segregation data are usually collected from different families exhibiting the same disease and pooled. The more families that can be examined, the greater the statistical significance of any evidence for linkage that can be obtained, and the greater the precision with which the distance between a linked DNA polymorphism and a disease allele can be measured. Most family studies have a maximum of about 100 individuals in whom linkage between a disease gene and a panel of DNA polymorphisms can be tested. This number of individuals sets the practical upper limit on the resolution of such a mapping study to about 1 centimorgan, or a physical distance of about 1 Mbp (1×10^6 bp).

Further Analysis Is Needed to Locate a Disease Gene in Cloned DNA

Although linkage mapping can usually locate a human disease gene to a region containing about 1 Mbp, as many as 10 different genes may be located in a region of this size. The ultimate objective of a mapping study is to locate the gene of interest within a cloned segment of DNA and then to determine the nucleotide sequence of this fragment. The relative scales of a chromosomal genetic map and physical maps corresponding to ordered sets of plasmid clones and the nucleotide sequence are shown in Figure 6-28.

FIGURE 6-28 Relationship between genetic and physical maps of a human chromosome. The diagram depicts a human chromosome analyzed at different levels of detail. The chromosome as a whole can be viewed in the light microscope when it is in a condensed state that occurs at metaphase, and the approximate location of specific sequences can be determined by fluorescence in situ hybridization (FISH). At the next level of detail, genetic traits can be mapped relative to DNA-based genetic markers. These genetic mapping studies usually do not pinpoint the gene identity because they localize genes with an accuracy of

only 1 cM, which would correspond to a region of about 1 M bp. To identify the sequence of a gene segment local segments of the chromosome carried on bacterial artificial chromosomes (BACs) can be analyzed at the level of DNA sequences. Important genetic differences are ultimately defined by differences in the nucleotide sequence of the chromosomal DNA.

One strategy for further localizing a disease gene within the genome is to identify mRNA encoded by DNA in the region of the chromosome under study. The aim is to find an mRNA that is altered or missing in various individuals affected with a disease compared with wild-type mRNA. Such an mRNA would be an excellent candidate for encoding the protein whose disrupted function causes that disease. One strategy is to compare the expression of the genes in the candidate region in tissues from normal and affected individuals to discover tissues in which a particular disease gene is expressed in normal individuals but not in affected individuals. The rationale here is that a mutation that phenotypically affects muscle, but no other tissue, might be in a gene that is expressed only in muscle tissue. As discussed in Section 6.5, the level of expression of mRNA is generally determined by in situ hybridization of labeled DNA or RNA to tissue sections, by microarray analysis, or by massively parallel sequencing of cDNAs (RNAseq). Each of these methods allows researchers to compare gene expression in mutant and wild-type tissues. Although the sensitivity of in situ hybridization is lower than other methods, it is able to identify an mRNA that is expressed at low levels in a given tissue but at very high levels in a subclass of cells within that tissue.

In many cases, point mutations may give rise to disease-causing alleles and yet result in no obvious change in the level of expression of mRNAs or change in length. In that case, researchers undertake a search for point mutations in the DNA regions encoding the mRNAs. Now that highly efficient methods for sequencing DNA are available, researchers frequently identify point mutations by determining the sequences of candidate regions of DNA isolated from affected individuals. The overall strategy is to search for a coding sequence that consistently shows possibly deleterious alterations in DNA from individuals that exhibit the disease. A limitation of this approach is that the region near the affected gene may carry naturally occurring polymorphisms unrelated to the gene of interest. Such polymorphisms, not functionally related to the disease, can lead to misidentification of the DNA fragment carrying the gene of interest. For this reason, the more mutant alleles available for analysis, the more likely that a gene will be correctly identified.

Most Inherited Diseases Result from Multiple Genetic Defects

Until now we have considered monogenic diseases; that is, a clearly discernible disease state is produced by a defect in a single gene. Monogenic diseases caused by mutation in one specific gene exhibit one of the characteristic inheritance patterns shown in Figure 6-26. Researchers have already mapped the genes associated with

hundreds of common monogenic diseases, including those listed in Table 6-1, using DNA-based markers as described previously.

However, many other inherited diseases show more complicated patterns of inheritance. The underlying genetic cause of such diseases is much more difficult to identify. One frequently encountered type of added complexity is *genetic heterogeneity*. In such cases, mutations in any one of several different genes can cause the same disease. For example, retinitis pigmentosa, which is characterized by degeneration of the retina usually leading to blindness, can be caused by mutations in any one of more than 60 different genes. In human linkage studies, data from multiple families must usually be combined to determine whether a statistically significant linkage exists between a disease gene and known molecular markers. Genetic heterogeneity such as that exhibited by retinitis pigmentosa can confound such an approach because any statistical trend in the mapping data from one family tends to be canceled out by the data obtained from another family with an unrelated causative gene.

Human geneticists used two different approaches to identify the many genes associated with retinitis pigmentosa. The first approach relied on mapping studies of exceptionally large families. Each family contained so many affected individuals that it was possible to provide statistically significant evidence for linkage between known DNA polymorphisms and a single one of the many potential

causative genes. From these studies geneticists found that several of the mutations that cause retinitis pigmentosa lie within genes that encode proteins that are abundant in the retina. Following up on this clue, when screening other individuals with retinitis pigmentosa geneticists concentrated their attention on those genes that are highly expressed in the retina. This approach of using additional information to focus screening efforts on a subset of candidate genes led to identification of additional, rare causative mutations in many different genes encoding retinal proteins.

Identifying Component Genetic Risk Factors of Complex Traits

The most common human disorders not caused by foreign infectious agents are heart disease, obesity, hypertension, diabetes, most cancers, and a variety of mental disorders. Although diet, behavior, and other environmental conditions clearly contribute to these diseases, the existence of a strong genetic component is suggested by the propensity of these diseases to run in families. The relative contribution of genetics, known as *heritability*, can be formally measured by calculating the proportion of genetically identical monozygotic twins who have been raised apart, but nevertheless both have the disease. For the diseases listed, most of the incidence of disease is heritable and the contribution of genetics is measured to be from 60 to 80 percent. In all but a few rare

instances, the disease shows a complex pattern of inheritance that cannot be explained by a single causative allele — thus the genetic component of these diseases is known as a *complex trait*. Alleles from multiple genes must be involved in the production of complex traits, and for this reason these genes and their alleles are referred to as *risk factors*. The systematic mapping of risk factors for complex traits in humans is one of the most important and challenging problems in human genetics, and we already know that for each of the diseases listed alleles of tens and even hundreds of different genes may be risk factors.

The most promising method of studying complex traits is to seek a statistical correlation between inheritance of a particular region of a chromosome and the propensity to have a disease, using a procedure known as a **genome-wide association study (GWAS)**. To see how a GWAS would work, consider the complex trait of type II diabetes. Very large samples are needed to obtain statistically significant results because of the enormous heterogeneity of possible genetic causes for type II diabetes. A typical experiment might include a case group of say 5000 individuals with type II diabetes would be compared to a socioeconomically matched control group of 5000 individuals with normal blood glucose homeostasis. The basic concept behind a GWAS is quite simple. The SNPs represented in these 10,000 individuals are surveyed to find those that have a small but significantly greater tendency to appear in individuals that have type II diabetes than in those that do not.

The power of this approach lies in computer algorithms that scan data from large numbers of individuals to identify small but significant correlations between a disease and inheritance of a particular region of the genome. A conceptually straightforward method to find all of the SNPs represented in the 10,000 case and control individuals would be to obtain and survey their complete genome sequences. At present, large-scale sequencing projects of this type are not yet practical. Rather, a typical GWAS will survey a set of 10^6 of the most common SNPs.

Even rare disease-causing alleles not included in the set of 10^6 common SNPs can be identified by GWAS by taking advantage of the phenomenon of linkage disequilibrium. When an allele that predisposes an individual to a disease arises by mutation, the allele will reside within the context of whatever particular set of SNPs was carried by the ancestral chromosome. Even many generations later, genetic recombination between the disease gene and nearby SNPs will be rare, and the disease-causing allele will tend to remain associated with the particular set of SNPs in the neighborhood of its chromosomal location. This lingering association of nearby genetic markers is known as *linkage disequilibrium* because not enough time has passed for genetic recombination to have caused the association between markers to be randomized or, in other words, to have come to equilibrium (Figure 6-29). Thus a risk factor for type II diabetes that itself is too rare to be included in the standard set of 10^6 SNPs

may nevertheless be found by associations with SNPs that are in linkage disequilibrium.

FIGURE 6-29 Linkage disequilibrium preserves the association between closely spaced SNPs. A new disease mutation arises in the context of an ancestral chromosome among a set of polymorphisms known as the *haplotype* of that chromosome (indicated by red shading; the blue segments of chromosomes represent general haplotypes derived from the general population and not from the ancestral haplotype in which the mutation originally arose). After many generations, chromosomes that carry the disease mutation will also carry segments of the ancestral haplotype that have not been separated from the disease mutation by recombination. The regions closest to the disease mutation are the most likely to be the ancestral haplotype. This phenomenon is known as *linkage disequilibrium*. The

position of the disease mutation can be located by scanning chromosomes that contain it for highly conserved polymorphisms corresponding to the ancestral haplotype.

GWAS can be a powerful tool to identify candidate genes that cause a predisposition to disease, but when all of the risk factors found by a typical GWAS are aggregated, usually they account for less than half of the total known heritability. Much of this missing heritability may eventually be accounted for by very rare SNPs or by factors that make such a small incremental contribution to the risk of disease that no significant association can be observed. As whole genome sequencing information becomes available for very large human cohorts, many more of these elusive risk factors should be found.

Medically Important Genes Can Be Identified by Alleles That Protect Against Disease

Until now, our discussion of human genes has centered on genes and alleles that cause inherited disease or increase its risk. The same technological advances that have accelerated the search for alleles that cause disease have enabled hunts for an equally important class of alleles that protect against disease. To illustrate the power of protective alleles, we will use the example of *PCSK9*, a gene recently found to play a key role in cholesterol homeostasis.

As described in Chapter 17, cholesterol moves through the bloodstream in lipoprotein particles known as LDL. High LDL levels in the blood can pose a risk of heart disease because excessive LDL can be deposited in coronary arteries as atherosclerotic plaque. *PCSK9* was first identified as a sequenced human gene that encodes a secreted protein with homology to a class of proteases. When it was discovered that a rare class of mutations that lead to increased LDL genetically mapped to *PCSK9*, a role in regulating cholesterol level was suspected. These mutated *PCSK9* alleles showed a dominant pattern of inheritance, implying that a gain of function leads to increased LDL. By extension of this logic, a loss of PCSK9 activity should decrease LDL levels. Sequencing the *PCSK9* gene in a large number of individuals to find frameshift and nonsense alleles confirmed that individuals with loss of function alleles did indeed have decreased LDL. Subsequent biochemical experiments have shown that the protein product of *PCSK9* negatively regulates the LDL receptor, which is responsible for transporting LDL from the blood into the liver by endocytosis. Inactivation of PCSK9 protein has been shown to dramatically decrease LDL levels and PCSK9 inhibitors have become a major target for cholesterol-lowering drugs. This great success in applying basic principles of human genetics to the discovery of the role of PCSK9 in cholesterol homeostasis has spurred interest in finding similar protective alleles for diabetes, obesity, and hypertension.

Identification of Causative Mutations in Cancer Cells

The cost of sequencing DNA has fallen so low that the entire genomes of cancer cells have been sequenced and compared with the genomes of normal cells from the same individuals in order to determine all the mutations that have accumulated in those persons' tumor cells. As discussed in Chapter 25, transformation of a normal cell into a cancer cell that divides without control usually requires multiple mutations. A major goal of sequencing cancer genomes is to identify all of the possible *driver* mutations implicated in transformation, but this approach is greatly complicated by the fact that transformed cells are usually defective in DNA repair and are prone to accumulate a large number of *passenger* mutations that do not contribute to cancer. To distinguish driver mutations from passenger mutations, investigators compared a large number of cancer genome sequences in an important application of the bioinformatic principles outlined in Section 6.3. The primary criterion for distinguishing driver mutations is that they are commonly present in all cancers, as well as commonly present in tumors from different patients with the same type of cancer (e.g., breast or colon cancer). A second criterion is based on the types of mutations that are found. A mutation in a driver gene would be expected to produce a significant change in gene function and may be a nonsense or frameshift mutation for a loss of function or a

missense mutation for a gain of function. In contrast, a mutation in a passenger gene is as likely as not to be a silent mutation.

KEY CONCEPTS OF SECTION 6.4

Locating and Identifying Genes That Specify Human Traits

- Inherited diseases and other traits in humans caused by a single gene show three major patterns of inheritance: autosomal dominant, autosomal recessive, and X-linked recessive (see Figure 6-26).
- Genes for human diseases and other traits can be mapped by determining their co-segregation with markers whose locations in the genome are known. The closer a gene is to a particular marker, the more likely they are to co-segregate (see Figure 6-27).
- Mapping of human genes with great precision requires thousands of molecular markers distributed along the chromosomes. The most useful markers are differences in the DNA sequence (polymorphisms) between individuals in noncoding regions of the genome, including single-nucleotide polymorphisms (SNPs) and short tandem repeats (STRs).
- Linkage mapping can often locate a human disease gene to a chromosomal region that includes as many as 10 genes. To identify the gene of interest within this candidate region typically requires expression analysis and comparison of DNA sequences between wild-type and disease-affected individuals.
- Some inherited diseases can result from mutations in different genes in different individuals (genetic heterogeneity).
- The most common inherited diseases depend on the presence of mutant alleles of multiple genes in the same individual. This type of disease is known as a complex trait and the alleles that contribute to the propensity for these diseases are known as risk factors. Risk factors can be mapped by finding a statistical correlation between the disease and a particular chromosomal location in a genome-wide association study.
- Genetic association studies can also identify alleles that protect against disease. Searching for alleles that protect against major inherited diseases is one of the most promising future directions of human genetics.
- Genomic sequencing of cancer cells reveals thousands of mutations that arise during the process of transformation into cancer cells. By comparing large numbers of cancer genome sequences, researchers can distinguish driver mutations, which contribute to

cell transformation, from passenger mutations, which do not contribute to cell transformation.

6.5 Using Cloned DNA Fragments to Study Gene Expression

In the previous sections, we described how to identify and characterize genes by analysis of mutations and by bioinformatic analysis of genome sequences. We also described the basic techniques for using recombinant DNA technology to isolate specific DNA clones and ways in which those clones can be further characterized. Here we consider how an isolated DNA clone can be used to study gene expression. We discuss several widely used general techniques that rely on nucleic acid hybridization to elucidate when and where genes are expressed, as well as methods for generating large quantities of protein and otherwise manipulating amino acid sequences to determine their expression patterns, structure, and function.

In Situ Hybridization Techniques Permit Detection of Specific mRNAs

Hybridization depends on the ability of complementary single-stranded DNA or RNA molecules to associate (hybridize) specifically with each other via base pairing. As discussed in Chapter 5, double-stranded (duplex) DNA can be denatured (melted) into single strands by heating in a dilute salt solution. If the temperature is then lowered and the ion concentration raised, complementary single

strands will reassociate (hybridize) into duplexes. In a mixture of nucleic acids, only complementary single strands (or strands containing complementary regions) will reassociate; moreover, the extent of their reassociation is virtually unaffected by the presence of noncomplementary strands. The power of the hybridization method comes from the ability to adjust the hybridization conditions so that only perfectly complementary sequences will hybridize.

One of the most basic ways to characterize a cloned gene is to determine when and where in an organism the gene is expressed. The expression of a particular gene can be followed by identifying in which cells or tissues its mRNA is found. One way to locate a gene's corresponding mRNA is to probe for it by hybridization to a specific complementary oligonucleotide that is fluorescently labeled. Thus an oligonucleotide of only about 20 nucleotides can be used to label a single unique complementary mRNA. To retain precise information about the location of the mRNA, a chemically fixed whole or sectioned tissue, or even a fixed whole permeabilized embryo, may be subjected to **in situ hybridization** to detect the mRNA encoded by a particular gene. By examining the fixed tissue in a fluorescence microscope, the amount of gene transcription can be monitored in both time and space (Figure 6-30).

EXPERIMENTAL FIGURE 6-30 In situ hybridization can detect activity of specific genes in whole and sectioned embryos. The specimen is made permeable to nucleic acids by treatment with detergent and a protease to expose the mRNA to the probe. A DNA or RNA probe, specific for the mRNA of interest, is made with nucleotide analogs containing chemical groups that can be recognized by antibodies. After the permeabilized specimen has been incubated with the probe under conditions that promote hybridization, the excess probe is removed with a series of washes. The specimen is then incubated in a solution containing an antibody that binds to the probe. This antibody is covalently joined to a reporter enzyme (e.g., horseradish peroxidase or alkaline phosphatase) that produces a colored reaction product. After excess antibody has been removed, substrate for the reporter enzyme is added. A colored precipitate forms where the probe has hybridized to the mRNA being detected. (a) A whole mouse embryo at about 10 days of development probed for *Sonic hedgehog* mRNA. The stain marks the notochord (red arrow), a rod of mesoderm running along the future spinal cord. (b) A cross section of a mouse embryo similar to that in part (a). The dorsal/ventral axis of the neural tube (NT) can be seen, with the notochord expressing *Sonic hedgehog* (red arrow) below it and the endoderm (blue arrow) still farther ventral. (c) A whole *Drosophila* embryo probed for an mRNA produced during trachea development. The repeating pattern of body segments is visible. Anterior (head) is up; ventral is to the left.

DNA Microarrays Can Be Used to Evaluate the Expression of Many Genes at Once

The expression of thousands of genes can be monitored simultaneously using DNA microarray analysis, another technique based on the concept of nucleic acid hybridization. A **DNA microarray** consists of an organized array of thousands of individual, closely packed sequences, each specific to a single gene, attached to the surface of a glass microscope slide. By coupling microarray analysis with the results from genomic sequencing projects, researchers can analyze the global patterns of gene expression in an organism during specific physiological responses or developmental processes.

Preparation of DNA Microarrays

In one method of preparing microarrays, a DNA segment of about 1 kb corresponding to part of the coding region of each of many genes to be analyzed is individually amplified by PCR. A robotic device is used to apply each amplified DNA sample to the surface of a glass microscope slide, which is then chemically processed to permanently attach the DNA sequences to the glass surface and to denature them. A typical array might contain some 6000 spots of DNA in a 2×2–cm grid.

In an alternative method, multiple DNA oligonucleotides, usually at least 20 nucleotides in length, are synthesized, each starting from an initial nucleotide that is covalently bound to the surface of a glass slide. The synthesis of an oligonucleotide of specific sequence can be programmed in a small region on the surface of the slide. Several oligonucleotide sequences corresponding to different regions of a single gene are thus synthesized in neighboring regions of the slide. Using this method, oligonucleotides representing thousands of genes can be produced on a single glass slide. Because the methods for constructing these arrays of synthetic oligonucleotides were adapted from methods for manufacturing microscopic integrated circuits used in computers, these types of oligonucleotide microarrays are often called *DNA chips*.

Using Microarrays to Compare Gene Expression Under Different Conditions

The initial step in a microarray expression study is to prepare cDNAs from the mRNAs expressed by the cells under study and attach fluorescent labels to them (see Figure 6-17). When the cDNA preparation is applied to a microarray under appropriate conditions, DNA spots representing genes that are expressed will hybridize to their complementary cDNAs in the labeled probe mix and can subsequently be detected in a scanning laser microscope.

Figure 6-31 depicts how this method can be applied to examine the changes in gene expression observed after starved human fibroblasts are transferred to a rich, serum-containing growth medium. In this type of experiment, the separate cDNA preparations from starved and from serum-grown fibroblasts are labeled with differently colored fluorescent dyes. A DNA microarray comprising 8600 mammalian genes is then incubated with a mixture containing equal amounts of the two cDNA preparations under hybridization conditions. After unhybridized cDNA is washed away, the intensity of green and red fluorescence at each DNA spot is measured using a fluorescence microscope and is recorded under the name of each gene according to its known position on the slide. The relative intensities of red and green fluorescence signals at each spot provide a measure of the relative level of expression of that gene in response to serum. Genes that are not transcribed under these growth conditions give no detectable signal. Genes that are transcribed at the same level under both conditions hybridize equally to both red- and green-labeled cDNA preparations. Microarray analysis of gene expression in fibroblasts showed that transcription of about 500 of the 8600 genes examined changed substantially after addition of serum.

EXPERIMENTAL FIGURE 6-31 DNA microarray analysis can reveal differences in gene expression in fibroblasts under different experimental conditions. (a) In this example, cDNA prepared from mRNA isolated from fibroblasts either starved for serum or after addition of serum is labeled with different fluorescent dyes. A microarray composed of DNA spots representing 8600 mammalian genes is exposed to an equal mixture of the two cDNA preparations under hybridization conditions. The ratio of the intensities of red and green fluorescence over each spot, detected with a scanning confocal laser microscope, indicates the relative expression of each gene in response to serum. (b) A micrograph of a small segment of an actual DNA microarray. Each spot in this 16×16 array contains DNA from a different gene hybridized to control and experimental cDNA samples labeled with red and green fluorescent dyes. (A yellow spot indicates equal hybridization of green and red fluorescence, indicating no change in gene expression.)

Cluster Analysis of Multiple Expression Experiments Identifies Co-Regulated Genes

Microarray studies reveal sets of genes that show similar patterns of gene expression; these genes are expressed at the same times in the same tissues. Genes that are expressed under the same conditions and in the same cell types are hence likely to be closely related functionally. However, a firm conclusion can rarely be drawn from a single microarray experiment. For example, many of the observed differences in gene expression just described in fibroblasts could be indirect consequences of the many different changes in cell physiology that occur when cells are transferred from one medium to another. In other words, genes that appear to be co-regulated in a single microarray expression experiment may undergo changes in expression for very different reasons and may actually have very different biological functions. A solution to this problem is to combine the information from a set of microarray expression experiments to find genes that are similarly regulated under a variety of conditions or over a period of time.

This more informative use of multiple microarray expression experiments is illustrated by examining the relative expression of the 8600 genes mentioned above at different times after serum addition to fibroblasts, which generated more than 10^4 individual pieces of data. A computer program, related to the one used to

determine the relatedness of different protein sequences, can organize these data and cluster genes that show similar expression over the time course after serum addition. This *cluster analysis* based on gene transcription efficiently groups sets of genes whose encoded proteins participate in a common cellular process, such as cholesterol biosynthesis or the cell cycle (Figure 6-32).

EXPERIMENTAL FIGURE 6-32 Cluster analysis of data from multiple microarray expression experiments can identify co-regulated genes. The expression of 8600 mammalian genes was detected by microarray analysis at time intervals over a 24-hour period after serum-starved fibroblasts were provided with serum. The cluster diagram shown here is based on a computer algorithm that groups genes showing similar changes in expression compared with a serum-starved control sample over time. Each column of colored boxes represents a single gene, and each row represents a time point. A red box indicates an increase in expression relative to the control; a green box, a decrease in expression; and a black box, no significant change in expression. The “tree” diagram at the top shows how the expression patterns for individual genes can be organized in a hierarchical fashion to group together the genes with the greatest similarity in their patterns of expression over time. Five clusters of coordinately regulated genes were identified in this experiment, as indicated by the bars at the bottom. Each cluster contains multiple genes whose encoded proteins function in a particular cellular process: cholesterol biosynthesis (A), the cell cycle (B), the immediate-early response (C), signaling and angiogenesis (D), and wound healing and tissue remodeling (E).

Microarray analysis is a powerful diagnostic tool in medicine. Previously indistinguishable disease variations are now detectable. For instance, particular sets of mRNAs have been found to distinguish tumors with a poor prognosis from those with a good prognosis. Analysis of these tumor biopsies will help physicians to select the most appropriate treatment. As more patterns of gene expression characteristic of various diseased tissues are recognized, the diagnostic use of DNA microarrays will be extended to other conditions. ■

Sequencing of cDNAs Allows Analysis of Gene Expression in Individual Cells

A limitation of DNA microarray analysis is that while hybridization is highly selective, it is relatively insensitive. Many mRNAs that are present but are of low abundance fail to produce a detectable signal. A powerful method is available that enables detection of mRNAs that are present at only one copy per cell. Known as **whole transcriptome shotgun sequencing** (or **RNA-Seq**), the method is to directly subject a large number ($>10^6$) cDNAs from a tissue to shotgun sequence analysis. A sequencing read of about 100 bases is obtained for each cDNA, which allows each read sequence to be unambiguously assigned to a particular mRNA. The method makes it possible to quantify relative mRNA abundance by simply counting the relative number of sequencing reads corresponding to each

mRNA. For example, when cDNA prepared from hepatocytes is subjected to RNA-Seq analysis, sequence reads corresponding to abundant mRNAs such as that for serum albumin may be detected thousands of times out of a total of a million reads. Since one read per million is used as the threshold for detection of very rare mRNAs, we can see that RNA-Seq can measure mRNA abundance over a range of 10^4-fold, which is far greater than any experiment based on hybridization could achieve.

Refinements of RNA-Seq, such as introducing a few rounds of amplification of cDNAs by PCR, have increased the sensitivity of the method so that RNA abundance even in single cells can be measured. This method, called **single cell RNA-Seq (scRNA-Seq)**, allows detection of differences in gene expression among individual cells that could be obscured when different cell types in a tissue are combined for preparation of a bulk mRNA sample.

E. coli Expression Systems Can Produce Large Quantities of Proteins from Cloned Genes

An important application of our knowledge of how to engineer genes for high levels of expression is the production of large quantities of useful proteins. Many protein hormones and other signaling or regulatory proteins are normally expressed at very low

concentrations and so cannot be isolated and purified in large quantities by standard biochemical techniques. To enable the widespread therapeutic use of such proteins, as well as basic research on their structure and functions, efficient procedures are needed for producing them in large amounts at reasonable cost. Recombinant DNA techniques that turn *E. coli* cells into factories for synthesizing low-abundance proteins are now used to produce commercially a variety of human proteins with therapeutic uses, including granulocyte colony-stimulating factor (G-CSF), insulin, growth hormone, and erythropoietin. For example, G-CSF stimulates the production of granulocytes, the phagocytic white blood cells that are critical to defense against bacterial infections. Administration of G-CSF to cancer patients helps offset the reduction in granulocyte production caused by chemotherapeutic agents, thereby protecting patients against serious infection while they are receiving chemotherapy. ■

The first step in producing large amounts of a low-abundance protein is to obtain a cDNA clone encoding the full-length protein by the methods (see Figure 6-17). The second step is to engineer plasmid vectors that will express large amounts of the encoded protein when they are inserted into *E. coli* cells. The key to designing such expression vectors is to include a promoter, a DNA sequence from which transcription of the cDNA can begin. Consider, for example, the relatively simple system for expressing G-CSF shown in Figure 6-33. In this case, G-CSF is expressed in *E. coli* transformed

with plasmid vectors that contain the *lac* promoter adjacent to the cloned cDNA encoding G-CSF. Transcription from the *lac* promoter occurs at high rates only when lactose, or a lactose analog, such as isopropylthiogalactoside (IPTG), is added to the culture medium. Even larger quantities of a desired protein can be produced in more complicated *E. coli* expression systems.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 6-33 Some eukaryotic proteins can be produced in *E. coli* cells from plasmid vectors containing the *lac* promoter. (a) This plasmid expression vector contains a fragment of the *E. coli* chromosome containing the *lac* promoter and the

neighboring *lacZ* gene. In the presence of the lactose analog IPTG, RNA polymerase normally transcribes the *lacZ* gene, producing *lacZ* mRNA, which is translated into the encoded protein, β-galactosidase. (b) The *lacZ* gene can be cut out of the expression vector with restriction enzymes and replaced by a cloned cDNA, in this case, one encoding granulocyte colony-stimulating factor (G-CSF). When the resulting plasmid is inserted into *E. coli* cells, addition of IPTG and subsequent transcription from the *lac* promoter produce G-CSF mRNA, which is translated into G-CSF protein.

To aid in purification of a eukaryotic protein produced in an *E. coli* expression system, researchers often modify the cDNA encoding the recombinant protein to make it easier to separate from endogenous *E. coli* proteins. For example, a short nucleotide sequence is commonly added to the end of the cDNA, so that the expressed protein will have six histidine residues at the C-terminus. Proteins modified in this way bind tightly to an affinity matrix that contains chelated nickel atoms, whereas *E. coli* proteins do not bind to such a matrix. The bound proteins can be released from the nickel atoms by decreasing the pH of the surrounding medium. In most cases, the modified protein is still functional, since addition of short amino acid sequences to either the C-terminus or the N-terminus of a protein usually does not interfere with the protein's biochemical activity.

Plasmid Expression Vectors Can Be Designed for Use in Animal Cells

Although bacterial expression systems can be used successfully to create large quantities of some proteins, bacteria are not suitable expression hosts in many cases. Many experiments are designed to examine the function of a protein in the context of an appropriate cell. In such cases, a genetically modified protein must be expressed in cultured animal cells. To accomplish this, genes are cloned into specialized eukaryotic expression vectors and are introduced into cultured animal cells by a process called **transfection**. Two common methods for transfecting animal cells differ in whether the recombinant vector DNA is or is not integrated into the host-cell genomic DNA.

In both methods, cultured animal cells must be treated to facilitate their initial uptake of the recombinant plasmid vector. This can be done by exposing cells to a preparation of lipids that penetrates the plasma membrane, increasing its permeability to DNA. Alternatively, cells are subjected to a brief electric shock of several thousand volts, a technique known as *electroporation* that makes the cells transiently permeable to DNA. Usually the plasmid DNA is added in sufficient concentration to ensure that a large proportion of the cultured cells will receive at least one copy. Researchers have also harnessed viruses for transfection; viruses can be modified to contain DNA of interest, which is then introduced into host cells by simply infecting them with the recombinant virus.

Transient Transfection

The simpler of the two transfection methods, called *transient transfection*, employs a plasmid vector similar to the yeast shuttle vectors described previously. For use in mammalian cells, plasmid vectors are engineered to carry a replication origin derived from a virus that infects mammalian cells, a strong promoter recognized by mammalian RNA polymerase, and the cloned cDNA encoding the protein to be expressed adjacent to the promoter (Figure 6-34a). Once such a plasmid vector enters a mammalian cell, the viral replication origin allows it to replicate efficiently, generating numerous plasmids from which the protein is expressed. However, during cell division, such plasmids are not faithfully segregated into both daughter cells, and in time, a substantial fraction of the cells in a culture will not contain a plasmid, hence the name *transient transfection*.

EXPERIMENTAL FIGURE 6-34 Transient and stable transfection with specially designed plasmid vectors permits expression of cloned genes in cultured animal cells. Both methods employ plasmid vectors that contain the usual elements — replication origin, selectable marker (e.g., amp^r), and polylinker — that permit propagation in *E. coli* as well as a cloned cDNA with an adjacent animal promoter. For simplicity, these elements are not depicted. (a) In transient transfection, the plasmid vector contains a replication origin from a virus that can replicate in the cultured animal cells. Since the vector is not incorporated into the genome of the cultured cells, production of the cDNA-encoded protein continues for only a limited time. (b) In stable transfection, the vector carries a selectable marker such as neo^r, which confers resistance to G-418. The relatively few transfected animal cells that integrate the exogenous DNA into their genomes are selected on medium containing G-418. Because the vector is integrated into the genome, these stably transfected, or transformed, cells will continue to produce the cDNA-encoded protein as long as the culture is maintained.

Stable Transfection (Transformation)

The second of the two transfection methods integrates the introduced vector into the genome of the host cell. In that case, the genome is permanently altered, and the cell is said to be *transformed*. Integration is most likely accomplished by endogenous enzymes that normally function in DNA repair and recombination. The basic procedure for expressing a cloned cDNA by *stable transfection* is outlined in Figure 6-34b. A commonly used selectable marker is the gene for neomycin phosphotransferase (designated neo^r), which confers resistance to a toxic compound chemically related to neomycin, known as G-418. In the presence of a high concentration of G-418, only those cells that have integrated the expression vector into the host chromosome will survive and give rise to a clone. Because the expression vector is integrated at random sites in the genome, individual transformed clones will differ in their rates of transcribing the inserted cDNA. Therefore, the stable transfectants are usually screened to identify those that produce the protein of interest at the highest levels.

Retroviral Expression Systems

Researchers have exploited the basic mechanisms used by viruses for inserting their genetic material into the host's chromosomal DNA to greatly increase the efficiency by which a modified gene can be stably expressed in animal cells. One such viral expression system is derived from a class of retroviruses known as *lentiviruses*.

The system utilizes lentivirus particles that carry an RNA version of the cloned gene incorporated into the virus's RNA genome. The cloned gene is flanked by lentivirus LTR sequences. In the target cell, the LTR sequences direct the copying of the RNA into double-stranded DNA by reverse transcription, resulting in the integration of that DNA into chromosomal DNA following a sequence of events depicted in Figure 7-14.

The key to the procedure is the production of lentivirus particles suitable for efficient introduction of a cloned gene into target animal cells. As shown in Figure 6-35, three different plasmids, introduced into cells by transient transfection, are used to produce recombinant lentivirus particles. The first plasmid, known as the *vector plasmid*, contains a cloned gene of interest next to a selectable marker such as neo^r flanked by lentivirus LTR sequences. The left LTR sequence directs synthesis of an RNA molecule that carries lentiviral LTR sequences at either end and thus has many of the properties of native retroviral RNA. In an appropriate host, this LTR-bearing RNA can be packaged into viral particles with the assistance of the other two plasmids. The second plasmid, known as the packaging plasmid, carries all of the viral genes except for the major viral envelope protein, necessary for packaging of LTR containing viral RNA into the nucleocapsid of a functional lentiviral particle. The final plasmid allows expression of a viral envelope protein that, when incorporated into a recombinant lentivirus, allows the resulting hybrid virus particles to infect a desired target cell type. A

common envelope protein used in this context is the glycoprotein of the vesicular stomatitis virus (VSV-G protein), which can readily replace the normal lentivirus envelope protein on the surface of completed virus particles. Virus particles coated with the VSV-G protein are able to infect a wide variety of mammalian cell types, including hematopoietic stem cells, neurons, and muscle and liver cells.

EXPERIMENTAL FIGURE 6-35 Retroviral vectors can be used for efficient integration of cloned genes into the mammalian genome. Recombinant lentiviral particles are produced in cells expressing viral proteins from a packaging plasmid and that include a coat protein that confers a broad host range expressed from the viral coat plasmid. These viral particles will package viral RNA synthesized from a vector plasmid that contains a gene sequence of interest. When a recombinant lentiviral particle formed in this way infects a recipient cell the

cloned gene of interest is introduced into the cell in a form that can integrate into chromosomal DNA and thus be stably expressed in the recipient cell.

After cell infection, the cloned gene flanked by the viral LTR sequences is reverse-transcribed into DNA, which is transported into the nucleus and then integrated into the host genome. If necessary, as in the case of stable transfection, cells with a stably integrated cloned gene and neo^r marker can be selected by resistance to G-418. Many of the techniques for inactivating the function of specific genes (see Section 6.6) require that an entire population of cultured cells be genetically modified simultaneously. Engineered lentiviruses are particularly useful for such experiments because they infect cells with such high efficiency that every cell in a population will receive at least one copy of the lentivirus-borne plasmid.

Gene and Protein Tagging

Expression vectors can provide a way to study the expression of eukaryotic proteins and their location with the cell. Such studies often rely on the use of a reporter protein, such as *green fluorescent protein (GFP)*, which can be conveniently detected in cells (see Figure 4-15). Here we describe two ways to create a hybrid gene that connects expression of the reporter protein to expression of the protein of interest. When the hybrid gene is reintroduced into cells, either by transfection with a plasmid expression vector containing

the modified gene or by creation of a transgenic animal as described in Section 6.6, the expression of the reporter protein can be used to determine where and when a gene is expressed. This method provides data similar to that from the in situ hybridization experiments described previously, but often with greater resolution and sensitivity.

Figure 6-36 illustrates the use of two different types of GFP-tagging experiments to study the expression of an odorant receptor protein in *C. elegans*. In the first type of experiment, the coding sequence of GFP is placed under control of the promoter for the odorant receptor in a configuration usually known as a *promoter-fusion*. In the second type of experiment, the coding sequence of GFP is linked directly to the coding sequence of the odorant receptor, in a configuration known as *protein-fusion.* When GFP is linked to the promoter, the GFP is expressed throughout specific neurons; thus this promoter fusion experiment provides readout of gene expression. But to look at the protein in the cell, protein-fusion methods are used. When GFP is linked to the odorant receptor coding sequence, it is localized at the distal cilia in sensory neurons, the site at which the receptor protein is normally located.

(a) Promoter-fusion; ODR10 promoter fused to GFP

Ashish Maurya.

(b) Protein-fusion; ODR10-GFP fusion protein

EXPERIMENTAL FIGURE 6-36 Gene and protein tagging facilitate cellular localization of proteins expressed from cloned genes. In this experiment, the gene encoding a chemical odorant receptor, *Odr10*, of *C. elegans* was fused to the gene encoding green fluorescent protein (GFP). (a) A promoter-fusion was generated by linking just the promoter of *Odr10* to the coding sequence for GFP. The result is that GFP is expressed in the cytoplasm of the same specific sensory neurons in the head of *C. elegans* where Odr10 is expressed. (b) A

protein-fusion was constructed by linking GFP to the end of the full-length Odr10 coding sequence. In this case, the Odr10-GFP fusion protein is targeted to the membrane at the tip of the sensory neurons and is apparent only at the distal end of the sensory cilia. The observed distribution can be inferred to reflect the normal location of Odr10 protein in specific neurons. Because the promoter-fusion shown in (a) lacks the Odr10 localization sequences, the expressed GFP fills the entire cell cytoplasm rather than being localized just to the distal tip of the sensory cilia.

An alternative to GFP tagging for detecting the location of a protein inside the cell is to modify the gene of interest by appending to it a short DNA sequence that encodes a short stretch of amino acids recognized by a known monoclonal antibody. Such a short peptide that can be bound by an antibody is called an *epitope*; hence this method is known as *epitope tagging*. After transfection of cells with a plasmid expression vector containing the modified gene, the expressed epitope-tagged form of the protein can be detected by immunofluorescence microscopy utilizing a monoclonal antibody specific for the epitope. The choice of whether to use a short epitope or GFP to tag a given protein often depends on what types of modification a cloned gene can tolerate and still remain functional.

GFP expressed in *C. elegans* can be imaged by fluorescent microscopy because the body of a living worm is transparent. To image gene expression in a larger animal such as the mouse a more sensitive bioluminescent reporter can be used. This method uses an enzyme derived from insects known as luciferase, which is responsible for the flashes of light emitted by fireflies. When provided with the substrate luciferin, luciferase will catalyze a

chemical reaction that produces visible light. Visible light photography can detect the light from a luciferase reporter emitted from within the body of a living mouse. The chapter opening figure shows a transgenic mouse expressing a promoter fusion of the T-cell specific promoter CD2 expressing luciferase.

KEY CONCEPTS OF SECTION 6.5

Using Cloned DNA Fragments to Study Gene Expression

- Hybridization of a labeled DNA to the complementary RNA or DNA sequence allows specific detection of a single mRNA species in the context of a whole cell.
- The presence and distribution of specific mRNAs within tissues can be determined by in situ hybridization and fluorescence microscopy.
- DNA microarray analysis simultaneously detects the relative levels of expression of thousands of genes in different types of cells or in the same cells under different conditions (see Figure 6-30).
- Cluster analysis of the data from multiple microarray expression experiments can identify genes that are similarly regulated under various conditions. Such co-regulated genes commonly encode proteins that have biologically related functions.
- RNA-Seq analysis, based on direct sequencing of millions of cDNAs, gives a picture of all of the mRNAs that are expressed in a single cell.
- Expression vectors derived from plasmids allow the production of abundant amounts of a protein from a cloned gene.
- Eukaryotic expression vectors can be used to express cloned genes in the context of a living organism. An important application of these methods is to the tagging of proteins with GFP or some other identifiable marker to determine the pattern of expression and intracellular location.

6.6 Altering the Function of Specific Genes by Design

The vast amount of genomic DNA sequence information obtained in recent years has led to the identification of many new genes. The function of a new gene can often be deduced from the similarity of the encoded proteins with proteins of known function, but its roles in the context of a living organism can't be known with certainty unless a mutant forms of the gene is available. In this section, we describe several ways of disrupting the normal function of a specific gene in the genome of an organism. Analysis of the resulting mutant phenotype often helps reveal the in vivo function of the normal gene and its encoded protein.

We will begin this section with a description of how gene deletions are constructed in yeast. Yeast is the most easily genetically manipulatable organism and is the first organism for which deletions for every gene have been constructed. This comprehensive collection of null alleles has allowed researchers to observe the effect of completely inactivating every gene in an organism. We will then turn to the recently developed, powerful genome editing method known as CRISPR, which is based on a bacterial system for making cuts in specific DNA sequences. This system has been adapted to edit specific genes in a wide variety of organisms, including mammals. The basic CRISPR protocol will cause a small deletion in the targeted gene, which usually generates a null allele.

Alternatively, gene researchers often desire to study the effect of a particular allele of a gene, such as a dominant gain of function allele, and CRISPR has been modified to carry out this more specific type of genome editing as well.

We will also describe other approaches that are used widely in model organisms to study the effects of gene inactivation: (1) use of transgenic mice to construct gene alleles that can be selectively inactivated in particular tissues and (2) promoting destruction of the mRNA transcribed from a gene using RNA interference.

Normal Yeast Genes Can Be Replaced with Mutant Alleles by Homologous Recombination

Modifying the genome of the yeast *S. cerevisiae* is particularly easy for two reasons: yeast cells readily take up exogenous DNA under certain conditions, and the introduced DNA is efficiently exchanged for the homologous chromosomal site in the recipient cell. This specific, targeted recombination of identical stretches of DNA allows any gene in yeast chromosomes to be replaced with a mutant allele.

In one popular method for disrupting yeast genes in this fashion, a gene is replaced by a selectable marker. PCR is used to generate a *disruption construct* containing the selectable marker, which is

subsequently transfected into yeast cells. As shown in Figure 6-37a, the two primers for PCR amplification of the selectable marker are each designed to include about 20 nucleotides identical to sequences flanking the yeast gene to be replaced. The resulting amplified construct comprises the selectable marker (e.g., the *KanMX* gene, which, like neo^r, confers resistance to G-418) flanked by about 20 bp at each end that match the ends of the target yeast gene. Once transfected into a diploid yeast cell, the disruption construct will typically replace one of the two copies of the target endogenous gene. These transformed diploid yeast cells can be identified by their resistance to G-418 or other selectable phenotype. Heterozygous diploid yeast cells generally grow normally regardless of the function of the target gene, but half the haploid spores derived from these cells will carry only the disrupted allele (Figure 6-37b). If a gene is essential for viability, then spores carrying a disrupted allele will not survive.

EXPERIMENTAL FIGURE 6-37 Homologous recombination with transfected disruption constructs can inactivate specific target genes in yeast. (a) A suitable construct for disrupting a target gene can be prepared using PCR. The two primers designed for this purpose each contain a sequence of about 20 nucleotides (nt) that is homologous to one end of the target yeast gene as well as sequences needed to amplify a segment of DNA carrying a selectable marker gene such as *kanMX*, which confers resistance to G-418. (b) When recipient diploid *Saccharomyces* cells are transformed with the disruption construct, homologous recombination between the ends of the construct and the corresponding chromosomal sequences integrates the marker gene into the chromosome, replacing the target-gene sequence. The recombinant diploid cells will grow on a medium containing G-418, whereas untransformed cells will not. If the target gene is essential for viability, half the haploid spores that form after sporulation of recombinant diploid cells will be nonviable.

Disruption of genes by this method is proving particularly useful in assessing the roles of proteins identified by analysis of the entire genomic sequence of *S. cerevisiae*. Each of the approximately 6000 genes has been disrupted with the *KanMX* construct in diploids, and gene disruptions in haploid spores have also been produced. These analyses have shown that about 4500 of the 6000 yeast gene disruptions can reside in viable haploid spores, revealing an unexpectedly large number of apparently nonessential genes. In some cases, disruption of a particular gene may give rise to subtle defects that do not compromise the viability of yeast cells growing under laboratory conditions. Alternatively, cells carrying a disrupted gene may be viable because of the operation of backup or compensatory pathways. The existence of compensatory pathways and processes is revealed through the analysis of double mutants as shown in Figure 6-10.

The construction of *KanMX* deletion constructs for *S. cerevisiae* included the insertion of two sequences of 20 nucleotides (nt) that are unique to each deleted gene. These sequences can be used as molecular bar codes that can be read out either by DNA sequencing or by hybridization to a microarray. By counting the number of copies of a given bar code the growth properties of the corresponding deletion mutant can be followed in a pooled mixture of all 4500 nonessential gene deletion mutants. In an early application of the bar code technology for parallel screening of

deletion mutants, the pool of all 4500 deletion mutants was tested for sensitivity to various stress conditions. For example, the pool was evaluated by hybridization to a microarray to determine the relative numbers of each deletion strain. After this initial calibration the pool was placed in growth medium containing 1 M NaCl, a condition that causes stress and will slow the growth of wild-type yeast. Deletion mutants that are less able to withstand salt stress will exhibit decreased fitness relative to the average strain when grown in 1 M NaCl. From among 4500 deletion strains 62 gene deletions were identified that exhibited a significant decrease in cell number as determined by counting the number of the corresponding bar codes after growth in 1 M NaCl. The typical approach to conducting an equivalent screen would be to test the growth of each of the 4500 deletion mutants individually, whereas this method of following each strain by its molecular bar code enables growth characteristics of the entire collection of mutants to be screened in a single culture flask. This efficient method for screening mutants can be applied whenever individual mutant strains can be identified by a unique sequence tag, as we will see in the next section on mutations generated by the CRISPR system.

Engineered CRISPR Systems Allow Precise Genome Editing

Precise alterations can be made in genomic DNA sequences, a process known as *genome editing,* of virtually all organisms through the use of CRISPR. This genome-editing technique is an adaptation of a natural mechanism that evolved to protect bacterial cells against foreign DNA, such as phage DNA. The name **CRISPR** (*c*lustered *r*egularly *i*nterspaced *s*hort *p*alindromic *r*epeats) refers to the curious arrays of tandem repeated sequences found in about half of the bacterial genomes that have been sequenced. The arrays of repeated sequences are flanked by a conserved set of genes, known as *Cas* (CRISPR-*as*sociated) genes, that show similarity to genes encoding nucleases.

The breakthrough in understanding the function of CRISPR sequences came from the observation that one set of repeated sequence elements in the array often matched short segments in phage genomes. It was subsequently shown that the CRISPR element and associated Cas genes confer on bacterial cells the ability to cleave phage DNA at precisely the site that corresponds to repeated sequences in the CRISPR array. By this means the bacterial cells acquire immunity to a phage. The acquisition of immunity takes place in two stages. In the first stage, a phage-infected bacterium cleaves the phage DNA into short segments and adds those segments to the CRISPR array so that they are interspersed with highly conserved repeats. In the second stage, transcription of the CRISPR array and processing of the resulting RNA yields mature bipartite RNA molecules, known as guide RNAs, that carry both the

conserved repeat sequences and a phage-derived spacer sequence. The guide RNA assembles with Cas proteins to form an interference complex, which can target infecting phage DNA (that has been released from the viral particle) through base pairing of the guide RNA and with its complementary sequence in the phage DNA. Once targeted to a specific DNA sequence, nucleases in the Cas proteins cleave both strands of the target DNA molecule at a site adjacent to the region base-paired with the guide sequence.

Using CRISPR to Modify Eukaryotic Genomes

Although CRISPR elements have been found only in prokaryotic organisms, researchers proposed that the guide RNA and Cas proteins should be able to perform their functions if expressed in eukaryotic cells. To adapt CRISPR to function in virtually any cell type, researchers have developed minimal systems consisting of the nuclease Cas9 and an engineered guide RNA (Figure 6-38a). Cas9 contains the enzymatic activities necessary for precise DNA cleavage, including two separate endonuclease activities — one for each strand of DNA. The guide RNA is composed of two regions: the first is a scaffold made up of two complementary sequences that form a double-stranded hairpin structure that binds to Cas9, and the second region of about 20 nt identifies the target sequence and is designed to perfectly match a specific target site in genomic DNA. When both Cas9 and the guide RNA are expressed in a recipient cell, Cas9 will cleave both DNA strands at the chromosomal site specified by the guide RNA sequence (Figure 6-38b, c). Transfection with

expression plasmids for Cas9 and a specific guide RNA has been shown to give rise to specific DNA cleavages in cells derived from a variety of organisms, including *Drosophila, C. elegans*, zebrafish, mouse, rat, and human.

FIGURE 6-38 Single-nucleotide mutations can be introduced into the genome using an engineered CRISPR-Cas9 system. (a) The genome of a target cell can be modified by expression of the double-stranded DNA endonuclease Cas9 and a guide RNA. Expression of these components can be achieved by transfection with plasmids carrying genes for Cas9

and the guide RNA or by direct injection of Cas9 mRNA and guide RNA. The guide RNA is composed of two parts: a sequence that folds into a hairpin scaffold structure that binds to Cas9, and a sequence of approximately 20 nt corresponding to the targeted site in the genome. (b) A complex of guide RNA bound to Cas9 is targeted to the genome by base pairing of the guide RNA with the complementary genomic DNA sequence. This structure allows the two distinct nuclease active sites of Cas9 to cleave both strands of the target DNA adjacent to the heteroduplex formed with the guide RNA. (c) By this mechanism, the expression of both Cas9 and a bipartite guide RNA designed to target a specific gene sequence leads to a double-strand cleavage of the target gene. (d) Cleaved DNA can be repaired via a nonhomologous end joining (NHEJ) process, which usually removes a small number of bases at the cleavage site. If the cleavage occurs in a coding sequence, NHEJ will usually inactivate gene function by producing a frameshift mutation. If an ~100-nt single-stranded DNA segment that spans the sequences flanking the cleavage site is injected along with Cas9 mRNA and the guide RNA, the cleaved DNA can be repaired by homologous recombination (homology-directed repair, HDR). By this mechanism, single base changes can be introduced into the repaired genomic DNA.

[Part (b) data from C. Anders et al., 2014, *Nature* **513**:569–573, PDB ID 4un3.]

A particularly efficient way to modify the germ line of a mouse begins with the microinjection of Cas9 mRNA and a guide RNA into a mouse zygote. The resulting double-strand break in the specific target sequence is typically repaired by a set of enzymes that ligate the free DNA ends back together in a process known as nonhomologous end joining (Figure 6-40d). Typically, a few base pairs are deleted at the site of cleavage because nucleases remove bases from the free DNA ends before the end joining reaction is completed. If the cleavage site is within a gene-coding sequence, the deletion of several bases will usually cause a frameshift mutation, thus producing a loss of function mutation that inactivates the targeted gene.

An important refinement of this method of genome editing allows exact single-base changes in the target DNA to be produced. This method first requires targeting Cas9 cleavage close to the site of the desired single-base change. With the addition of a segment of DNA, typically about 100-nt long, that matches the sequences flanking the cleavage site and contains the desired single base mutation, the free ends can be repaired by homologous recombination using the added homologous DNA segment, leaving the single-base mutation in the repaired DNA (see Figure 6-40d). In a dramatic demonstration of this genome editing method, a single-base mutation was corrected in *Crygc*, a gene for gamma-crystallin that leads to the formation of cataracts. The mutated allele was corrected back to the wild-type form by injection of a mutant mouse zygote with Cas9 mRNA, a guide RNA that directs cleavage at the site of the mutation, and a 90-nt DNA segment spanning the cleavage site and containing the wild-type *Crygc* sequence. This experiment also illustrates the remarkable selectivity of CRISPR-Cas9 targeting, since the guide RNA was able to discriminate between the mutant and wild-type alleles even though they differed by only one base pair.

Genome-Wide CRISPR Screens

The ability of CRISPR genome editing to produce genetically modified mammals, including humans, has sparked both public interest and controversy. But from the perspective of cell biologists hoping to learn more about cell function, genome editing by CRISPR

of somatic cells grown in culture is a powerful (and not at all controversial) research tool for exploring the function of mammalian genes in the context of a living cell. One of the most significant extensions of genome editing to somatic cells is the ability to test in a single experiment the effects of loss of function mutations in each of approximately 20,000 mammalian genes. One way to do this would be to transfect cultured cells with the gene for Cas9 and a gene for a guide RNA specifically targeting an exon of a selected gene. To test for the effects of loss of function of each of 20,000 mammalian genes would require 20,000 different transfections and 20,000 different phenotypic assays of the CRISPR edited cell lines. As was the case for screening the collection of yeast gene deletions, a much more efficient way to conduct such a screen would be to pool all 20,000 transfected cell lines and then to use the sequence of the guide RNA as a unique molecular tag to follow the growth of each individual cell line.

To see how such a pooled screen would work, suppose we wanted to identify genes that, when mutated, conferred resistance to Taxol, an anticancer drug which interferes with the function of microtubules during cell division. First, a collection of cells transfected with genes for Cas9 and with a guide RNA for each of 20,000 different genes is generated as a large pool. Next DNA isolated from the pool is subjected to large-scale sequencing of the transfected guide RNA genes such that $>10^6$ separate guide RNA gene sequences are determined from the pool. The relative number of reads corresponding to each specific guide RNA will give a count of the

relative numbers of cells carrying each guide RNA and provide a baseline for the experiment. After pooled cells have been exposed to Taxol for a period of time long enough for the number of Taxol-sensitive cells to decline substantially (e.g., 36 hours), the guide RNA genes in the pool are sequenced again. The typical cell line would decrease in relative number compared to a baseline determined at the start of the experiment because sensitivity to Taxol would have slowed cell growth. However, the relative number for some cell lines would increase after Taxol treatment. These would contain guide RNA genes that promote mutations that increase resistance to Taxol. Some cell lines would show an even greater decrease in relative number relative to the average cell line; this would indicate that the corresponding guide RNA genes promoted mutations that cause hypersensitivity to Taxol. Thus in a single large experiment, the effect of CRISPR inactivation of every gene in the mammalian genome can be tested for increased resistance or sensitivity to Taxol — an important advance in identifying all of the genes that may play a role in modulating the efficacy of Taxol as an anticancer agent.

Inducible Activation of CRISPR

A significant limitation of genome editing using CRISPR, which generally produces loss of function mutations, is that mutations in essential genes are difficult to study. Moreover, for some genes, it is often desirable to study the effects of gain-of-function alleles. Examples are the genes for proteins involved in signal transduction or gene regulation. In such cases, it is desirable to transiently

increase or decrease the expression of a given gene rather than permanently inactivate it by genome editing. The CRISPR system has been adapted for this purpose through the development of two different systems, one for transiently decreasing gene expression and one for increasing it. One system, known as CRISPRi, targets Cas9 to the promoter so as to interfere with transcription initiation, whereas a complementary gene-activating system, known as CRISPRa, activates transcription of a gene of interest by delivering a transcriptional activation domain to its promoter (Figure 6-39). Both CRISPRi and CRISPRa employ a modified version of Cas9 with the endonuclease activity inactivated (this nuclease dead form is called *dCas9*). When dCas9 is targeted to the promoter region of a gene by transiently expressing an appropriate guide RNA, dCas9 will bind to the promoter without cleaving the DNA. For CRISPRi, dCas9 is targeted to a region of the promoter that will directly compete with the ability of RNA polymerase to initiate transcription and thus will transiently interfere with gene expression. For CRISPRa, dCas9 is fused to a powerful transcription activation domain that will cause a transient activation of gene expression when this hybrid protein is targeted to a promoter.

FIGURE 6-39 CRISPR-Cas9 engineered to produce transient inactivation or hyperactivation of a gene. (a) CRISPR interference (CRISPRi) can be used to inactivate transcription of a specific gene. For CRISPRi, a synthetic guide RNA is designed to target the RNA polymerase binding region within the promoter for a gene of interest. When this guide RNA is expressed together with a mutated form of Cas9 that lacks endonuclease activity (dCas9), the guide RNA will direct dCas9 to bind to the promoter, preventing RNA

polymerase from binding and thus blocking transcription of the gene. (b) CRISPRa employs a similar strategy except that the region targeted by the guide RNA is upstream of the promoter of interest and dCas9 is fused to a powerful transcription activation domain (dCas9-VP16). When dCas9-VP16 is targeted to the promoter region of the gene of interest the activation domain will activate transcription of that gene.

Somatic Cell Recombination Can Inactivate Genes in Specific Tissues of Mice

The same principles applied to genetically modify yeast by homologous recombination can be applied to mammalian genes. The use of homologous recombination to replace a normal mouse gene by a gene knockout has been a historically important way to construct null alleles of mouse genes, but these methods have been largely replaced by the powerful CRISPR-Cas9 genome editing methods. However, investigators are often interested in examining the effects of knockout mutations in a particular tissue of the mouse, at a specific stage in development. The problem is that mice carrying a germ-line mutation may have defects in numerous tissues or die before the developmental stage of interest. To address this problem, mouse geneticists have devised a clever technique to inactivate target genes in specific types of somatic cells or at particular times during development.

In the first stage of this procedure, a DNA construct containing a specifically modified allele of a particular target gene is introduced into embryonic stem (ES) cells. These cells, which are derived from the blastocyst, can be grown in culture through many generations (see Figure 22-6). In a small fraction of transfected cells, the introduced DNA undergoes homologous recombination with the target gene, although recombination at nonhomologous chromosomal sites occurs much more frequently. To enable selection for cells in which the construct allele has successfully replaced the target gene, the recombinant DNA construct introduced into ES cells includes the selectable marker (neo^r), which confers resistance to G-418. To produce mice carrying this construct in their genome, modified ES cells are injected into a recipient wild-type mouse blastocyst, which subsequently is transferred into a pseudopregnant female mouse. The resulting progeny will be chimeras, containing tissues derived from both the transplanted ES cells and the host cells. Chimeric mice are then mated with mice that are homozygous for another allele of the marker trait to determine if the knockout mutation has been incorporated into the germ line. Finally, mating of mice, each heterozygous for the knockout allele, will produce progeny homozygous for the knockout mutation.

Homologous recombination can also be used to produce a mouse in which the gene of interest has been inactivated in only a single tissue. This technique employs short DNA recombination sites

(called loxP *sites*) and the enzyme Cre that catalyzes recombination between them. The loxP-*Cre recombination system* is derived from bacteriophage P1, but this site-specific recombination system also functions when placed in mouse cells. An essential feature of this technique is that expression of Cre is controlled by a promoter specific to a single cell type. In *loxP*-Cre mice generated by the procedure depicted in Figure 6-40, inactivation of the gene of interest (X) occurs only in cells in which the promoter controlling the *cre* gene is active. By using different promoters, researchers can study the effects of knocking out gene X in various types of cells.

EXPERIMENTAL FIGURE 6-40 The *loxP*-Cre recombination system can knock out genes in specific cell types. The outlined protocol is designed to produce a knockout of a target gene (GeneX) targeted to a specific cell type. A a *loxP* mouse contains the conditional gene X knockout generated by inserting *loxP* sites (purple) on each side of an essential exon (exon 2) of the target gene (blue). Since the *loxP* sites are in introns, they do not disrupt the function of gene X. The Cre mouse carries the *cre* gene (orange) from bacteriophage P1 expressed from a mouse promoter specific for the desired cell-type (yellow). The *cre* gene is incorporated into the mouse genome by nonhomologous recombination and does not affect the function of endogenous mouse genes. The Cre mouse is also heterozygous for a gene X knockout allele. Crossing these two strains generates among the progeny *loxP*-Cre mice that contain as the only functional copy of gene X the conditional knockout construct as well as having regulated expression of cre. Cre protein produced only in those cells in which the

promoter is active will catalyze recombination between the *loxP* sites, leading to deletion of exon 2 and a complete loss of function of gene X in all cells expressing Cre.

An early application of this technique provided strong evidence that a particular neurotransmitter receptor is important for learning and memory. Previous pharmacological and physiological studies had indicated that normal learning requires the NMDA class of glutamate receptors in the hippocampus, a region of the brain. But mice in which the gene encoding an NMDA receptor subunit was knocked out died shortly after birth, precluding analysis of the receptor's role in learning. Following the protocol in Figure 6-40, researchers generated mice in which the receptor subunit gene was inactivated in the hippocampus but expressed in other tissues. These mice survived to adulthood and showed learning and memory defects, confirming a role for these receptors in the ability of mice to encode their experiences into memory.

RNA Interference Causes Gene Inactivation by Destroying the Corresponding mRNA

First observed in the roundworm *C. elegans*, **RNA interference (RNAi)** refers to the ability of double-stranded RNA to block expression of its corresponding single-stranded mRNA, but not that of mRNAs with a different sequence. The phenomenon provides a

straightforward method to inhibit transiently the function of specific genes.

As described in Chapter 9, the phenomenon of RNAi rests on the ability of eukaryotic cells to cleave double-stranded RNA into short (23-nt) double-stranded segments known as small inhibitory RNAs (siRNAs). The RNA endonuclease that catalyzes this reaction, known as Dicer, is found in all metazoans, but not in simpler eukaryotes such as yeast. The siRNA molecules, in turn, can cause cleavage of mRNA molecules of matching sequence, in a reaction catalyzed by a protein complex known as *RISC*. Attached to RISC, one strand of the siRNA recognizes and hybridizes with its complementary sequence on the target mRNA; subsequently, specific nucleases in the RISC complex cleave the mRNA-siRNA hybrid. This model accounts for the specificity of RNAi, since it depends on base pairing, and for its potency in silencing gene function, since the complementary mRNA is permanently destroyed by nucleolytic degradation. The normal function of both Dicer and RISC is to allow for gene regulation by small endogenous RNA molecules known as *microRNAs*, or *miRNAs*.

Researchers can exploit the microRNA pathway to intentionally silence a *C. elegans* gene of interest by using either of two general methods for generating siRNAs of defined sequence. In the first method, a double-stranded RNA corresponding to the target-gene sequence is produced by in vitro transcription of both sense and antisense copies of that sequence (Figure 6-41a). This dsRNA is then

injected into the gonad of an adult worm, where it is converted to siRNA by Dicer in the developing embryos. In conjunction with the RISC complex, the siRNA molecules cause the corresponding mRNA molecules to be destroyed rapidly. The resulting worms display a phenotype similar to the one that would result from disruption of the target gene itself. In some cases, insertion of just a few molecules of a particular dsRNA into a cell is sufficient to inactivate many copies of the corresponding mRNA. Figure 6-41b illustrates the ability of an injected dsRNA to interfere with the production of the corresponding endogenous mRNA in *C. elegans* embryos. In this experiment, the mRNA levels in embryos were determined by in situ hybridization, as described earlier, using a fluorescently labeled probe.

(c) In vivo production of double-stranded RNA

EXPERIMENTAL FIGURE 6-41 RNA interference (RNAi) can inhibit gene function in *C. elegans* and other organisms. (a) In vitro production of double-stranded RNA (dsRNA) for interference with a specific target gene. The coding sequence of the gene, derived from either a cDNA clone or a segment of genomic DNA, is placed in two orientations in a plasmid vector adjacent to a strong promoter. Transcription of both constructs in vitro using RNA polymerase and ribonucleoside triphosphates yields many RNA copies in both the sense orientation (identical to the mRNA sequence) and the complementary antisense orientation. Under suitable conditions, these complementary RNA molecules hybridize to form dsRNA. When the dsRNA is injected into cells, it is cleaved by Dicer into siRNAs. (b) Inhibition of *mex3* RNA expression in *C. elegans* embryos by RNAi (see the text for the mechanism). Expression of *mex3* RNA in embryos was assayed by in situ hybridization to a probe specific for this mRNA, linked to an enzyme that produces a colored (purple) product. (*Left*) Wild-type embryo. (*Right*) Embryo derived from a worm injected with double-stranded *mex3* RNA. Each four-cell-stage embryo is ~50 mm in length. (c) In vivo production of double-stranded RNA via an engineered plasmid introduced directly into cells. The synthetic gene construct is a tandem arrangement of both sense and antisense sequences of the target gene. When it is

transcribed, double-stranded small hairpin RNA (shRNA) forms. The shRNA is cleaved by Dicer to form siRNA.

[Reprinted by permission from Macmillan Publishers Ltd, from A. Fire, 1998. Potent and specific genetic interference by double-stranded RNA in *Caenorhabditis elegans*. *Nature*, **391**(6669):806–811; permission conveyed through Copyright Clearance Center, Inc.]

The second method is to produce a specific double-stranded RNA in vivo. An efficient way to do this is to express a synthetic gene that is designed to contain tandem segments of both sense and antisense sequences corresponding to the target gene (Figure 6-41c). When this gene is transcribed, a double-stranded RNA hairpin structure forms, known as *small hairpin RNA*, or *shRNA*. The shRNA will then be cleaved by Dicer to form siRNA molecules. The lentiviral expression vectors are particularly useful for introducing synthetic genes for the expression of shRNA constructs into animal cells.

Both RNAi methods lend themselves to systematic studies in which researchers inactivate each of the known genes in an organism and observe what goes wrong. For example, in initial studies with *C. elegans*, RNA interference with 16,700 genes (about 86 percent of the genome) yielded 1722 visibly abnormal phenotypes. The genes whose functional inactivation causes particular abnormal phenotypes can be grouped into sets; each member of a set presumably controls the same signals or events. The regulatory relations between the genes in a set — for example, the genes that control muscle development — can then be worked out.

RNAi-mediated gene inactivation has been successful in many organisms, including *Drosophila*, many kinds of plants, zebrafish, the frog *Xenopus*, and mice, and these organisms are now the subjects of large-scale RNAi screens. For example, lentiviral vectors have been designed to inactivate by RNAi more than 10,000 different genes expressed in cultured mammalian cells. The functions of the inactivated genes can be inferred from defects in the growth or morphology of cell clones transfected with lentiviral vectors.

KEY CONCEPTS OF SECTION 6.6

Altering the Function of Specific Genes by Design

- Once a gene has been cloned, important clues about its normal function in vivo can be deduced from the observed phenotypic effects of mutating the gene.
- Genes can be disrupted in yeast by inserting a selectable marker gene into one copy of a wild-type gene via homologous recombination, producing a heterozygous mutant. When such a heterozygote forms spores, two nonviable haploid spores will be produced (see Figure 6-37).
- Each yeast gene deletion has been tagged with a unique DNA sequence that can serve as a molecular bar code that allows the growth of individual deletion strains to be traced in a pooled population containing all of the deletion strains.
- A bacterial system that evolved to precisely target and cleave foreign DNA, known as CRISPR, has been adapted for introducing specific changes in the genomic DNA of many organisms. Cleavage of chromosomal DNA at a specific site by CRISPR-Cas9 usually results in a short deletion at the cleavage site. If an appropriately designed DNA segment is provided by transfection, specific DNA changes, such as point mutations, can be introduced at the cleavage site (see Figure 6-39).
- All genes in the mammalian genome can be disrupted by CRISPR-Cas9 genome editing, and the growth properties of specific gene disruptions in a pooled population can be traced.
- Cas9 protein with an inactivated nuclease can be used for the transient interference (CRISPRi) or activation (CRISPRa) of a targeted gene.

- In mice, modified genes can be incorporated into the germ line at their original genomic location by homologous recombination. The *loxP*-Cre recombination system permits production of mice in which a gene is knocked out in a specific tissue.
- In many organisms, including the roundworm *C. elegans*, double-stranded RNA triggers destruction of the all the mRNA molecules with the same sequence. This phenomenon, known as RNAi (RNA interference), provides a specific and potent means of inactivating genes without altering their structure.

Review the Concepts

1. Genetic mutations can provide insights into the mechanisms of complex cellular or developmental processes. How might your analysis of a genetic mutation be different depending on whether a particular mutation is recessive or dominant?
2. What is a temperature-sensitive mutation? Why are temperature-sensitive mutations useful for uncovering the function of a gene?
3. Describe how complementation analysis can be used to reveal whether two mutations are in the same or in different genes. Explain why complementation analysis will not work with dominant mutations.
4. Restriction enzymes and DNA ligase play essential roles in DNA cloning. How is it that a bacterium that produces a restriction enzyme does not cut its own DNA? Describe some general features of restriction sites. What are the three types of DNA ends that can be generated after cutting DNA with restriction enzymes? What reaction is catalyzed by DNA ligase?
5. Bacterial plasmids often serve as cloning vectors. Describe the essential features of a plasmid vector. What are the advantages and applications of plasmids as cloning vectors?
6. A DNA library is a collection of clones, each containing a different fragment of DNA, inserted into a cloning vector. What is the difference between a cDNA library and a genomic DNA library? Suppose you would like to clone

gene X, a gene expressed only in neurons, into a vector using a library as the source of the insert. You have the following libraries at your disposal: a genomic library from skin cells, a cDNA library from skin cells, a genomic library from neurons, and a cDNA library from neurons. Which could you use, and why?

7. In 1993, Kary Mullis won the Nobel Prize in Chemistry for his invention of the PCR process. Describe the three steps in each cycle of a PCR reaction. Why was the discovery of a thermostable DNA polymerase so important for the development of PCR?
8. A number of foreign proteins have been expressed in bacterial and mammalian cells. Describe the essential features of a recombinant plasmid that are required for expression of a foreign gene. How can the foreign protein be modified to facilitate its purification? What is the advantage of expressing a protein in mammalian cells versus expressing the same protein in bacteria?
9. RT-PCR and microarrays can be used to analyze gene expression. A lab studies yeast cells, comparing their growth in two different sugars, glucose and galactose. One student is comparing expression of the gene *HMG2* under these two conditions. Which technique(s) could he use and why? Another student wants to compare expression of all the genes on chromosome 4, of which there are approximately 800. What technique(s) could she use and why?

10. What are paralogous and orthologous genes? What are some of the explanations for the finding that humans are a much more complex organism than the roundworm *C. elegans*, yet have only 5 percent more protein-coding genes (21,000 versus 20,000)?
11. In determining the identity of the protein that corresponds to a newly discovered gene, it often helps to know the pattern of tissue expression for that gene. For example, researchers have found that a gene called *SERPINA6* is expressed in the liver, kidney, and pancreas but not in other tissues. What techniques might researchers use to find out which tissues express a particular gene?
12. DNA polymorphisms can be used as DNA markers. Describe the differences between SNPs and STR polymorphisms. How can these markers be used for DNA-mapping studies?
13. How can linkage-disequilibrium mapping sometimes provide a much higher resolution of gene location than classical linkage mapping?
14. Genetic linkage studies can usually locate the chromosomal position of a disease gene only roughly. How can expression analysis and DNA sequence analysis help locate a disease gene within the region identified by linkage mapping?
15. The ability to selectively modify the genome in the mouse has revolutionized mouse genetics. Outline the procedure for generating a knockout mouse at a specific genetic locus. How can the *loxP*-Cre system be used to conditionally

knock out a gene? What is an important medical application of knockout mice?

16. Two methods for functionally inactivating a gene without altering the gene sequence involve dominant-negative alleles and RNA interference (RNAi). Describe how each method can inhibit expression of a gene.

CHAPTER 7

Genes, Chromatin, and Chromosomes

L. Willatt/Science Source.

These brightly colored FISH-painted chromosomes are not only beautiful, but also useful in revealing chromosome anomalies and in comparing karyotypes of different species.

OUTLINE

7.1 Eukaryotic Gene Structure and Organization

7.2 Chromosomal Organization of Genes and Noncoding DNA
7.3 Transposable (Mobile) DNA Elements
7.4 Structural Organization of Eukaryotic Chromatin and Chromosomes
7.5 Morphology and Functional Elements of Eukaryotic Chromosomes

In previous chapters, we learned how the structure and composition of proteins allow them to perform a wide variety of cellular functions. We also examined another vital component of cells, nucleic acids, and the process by which information encoded in the sequence of DNA is translated into protein. In this chapter, our focus again is on DNA and proteins as we consider the characteristics of eukaryotic nuclear genomes. The chapter is organized around two major topics: (1) the organization and evolution of genetic information and (2) the structure and function of chromatin and chromosomes; the former being the complex of nuclear DNA and abundant nuclear proteins, and the latter being those structures that condense and become visible by light microscopy during mitosis.

By the beginning of the twenty-first century, biologists had complete genome sequences of hundreds of viruses, scores of bacteria, and one unicellular eukaryote, the budding yeast *Saccharomyces cerevisiae*. Today the vast majority of the genomic sequence is also known for the fission yeast *Schizosaccharomyces pombe*; many other fungi; the model plant organism *Arabadopsis thaliana*; multiple other plants; multicellular animals (metazoans), including the roundworm *Caenorhabditis elegans*, the fruit fly *Drosophila melanogaster*, mice,

humans, and hundreds of other vertebrates and invertebrates, with at least one representative from each of the 35 or so metazoan phyla. Detailed analysis of these sequencing data has led to insights into evolution, genome organization, and gene function. It has also allowed researchers to identify previously unknown genes and to estimate the total number of protein-coding genes in each of the sequenced genomes. Comparisons among gene sequences often provide insight into possible functions of newly identified genes.

It was a surprise to many researchers when genomic sequencing revealed that large portions of the genomes of metazoans and plants do not encode mRNAs or any other RNAs required by the organism. Remarkably, about 98.5 percent of human chromosomal DNA is noncoding DNA! The noncoding DNA includes transcription regulatory sequences recognized and bound by proteins that regulate transcription of genes within tens to hundreds of kb away in the linear DNA sequence. However, the vast majority of noncoding DNA in multicellular organisms includes many regions that do not seem to be involved directly in gene control or DNA replication. A large fraction of noncoding DNA in the genomes of individual organisms (~50 percent for humans) includes many regions that are similar but not identical in sequence to one another. There is enough variation within this *repetitive DNA* among individuals that every person can be distinguished by a unique DNA *fingerprint* based on these sequence variations. Moreover, the location in the genome of some repetitive DNA sequences varies

among different individuals of the same species. At one time, all noncoding DNA was collectively termed *junk DNA* and was considered to serve no purpose. We now understand the evolutionary basis of this noncoding DNA and its variation in location among individuals. Cellular genomes harbor transposable (mobile) DNA elements that can copy themselves and move to new locations throughout the genome. Although most transposable DNA elements seem to have little function in the life cycle of an individual organism, over evolutionary time they have helped to shape our genomes and contributed to the rapid evolution of multicellular organisms.

A eukaryotic genome is made up of very long molecules of DNA. For example, the 46 chromosomes in a human cell contain about 2 m of DNA (which is the height of someone six and a half feet tall). All of this DNA must be contained within a nucleus whose diameter is less than 20 μm; a compaction ratio of greater than 100,000 to 1. Specialized proteins associated with nuclear DNA fold and organize the DNA so that it fits into a nucleus. And yet, at the same time, any given portion of this highly compacted DNA can be accessed readily for transcription, replication, and repair of damage without the long DNA molecules becoming tangled or broken. Furthermore, the integrity of DNA must be maintained during the process of cell division when the entire genome is replicated and partitioned into daughter cells. In eukaryotes, the complex of DNA and the proteins that bind and organize the DNA is called *chromatin.* During mitosis,

chromatin can be visualized by light microscopy as individual chromosomes. As we will see in this and the following chapter, the organization of DNA into chromatin enables mechanisms of gene regulation that are not available in bacteria.

In the first three sections of this chapter, we walk through the landscape of eukaryotic genes and genomes. First we discuss the structure of eukaryotic genes and the complexities that arise in multicellular organisms from processing mRNA precursors into alternatively spliced mRNAs. Next we discuss the main sequence classes of eukaryotic DNA, including the special properties of transposable DNA elements and how they have shaped contemporary genomes. The final two sections of the chapter address how DNA is physically organized in eukaryotic cells. We consider how DNA and histone proteins are packaged into the compact complexes called *nucleosomes*, we describe the large-scale structure of chromosomes, and we look at the functional elements required for chromosome duplication and segregation. Figure 7-1 provides an overview of these interrelated subjects. The understanding of genes, chromatin, and chromosomes gained in this chapter will prepare you to explore in the following two chapters how the synthesis and amount of each protein and functional RNA in a cell is regulated.

FIGURE 7-1 Overview of the structure of genes and chromosomes. DNA of multicellular eukaryotes consists of both unique and repeated sequences. Each chromosome consists of a single, long molecule of DNA (as long as 280 Mb in humans), organized into nucleosomes that fold and interact to generate various levels of chromatin condensation. This compaction process is carried out by the histone and nonhistone proteins that interact with the DNA molecule. The combination of a DNA molecule, histone proteins, and nonhistone proteins is called chromatin. Each chromosome occupies its own *territory* in the nucleus (note the blue, purple, and red chromosomes visible in the nucleus).

7.1 Eukaryotic Gene Structure and Organization

In molecular terms, a *gene* is commonly defined as *the entire nucleic acid sequence that is necessary for the synthesis of a functional gene product (polypeptide or RNA)*. According to this definition, a gene includes more than the nucleotides encoding an amino acid sequence or a functional RNA, which is referred to as the *coding region*. A gene also includes all of the DNA sequences required for synthesis of a particular RNA transcript, no matter where those sequences are located in relation to the coding region. For example, in genes of multicellular animals, transcription-control regions known as **enhancers** can lie 50 kb or more from the coding region. As we learned in Chapter 5, other critical noncoding regions in eukaryotic genes include **promoters**, which determine where transcription initiates on a DNA template; *poly(A) sites* that specify 3′ cleavage and polyadenylation, generating the 3′-end of an mRNA; and *splice sites* where exons in pre-mRNA molecules are spliced together (see Figure 5-27). Since these noncoding regions control transcription initiation and RNA processing, mutations in these sequences affect the normal expression and function of RNAs, producing distinct phenotypes in mutant organisms, even though the coding regions of the associated genes are normal. We examine these various transcription-control elements and mechanisms

regulating post-transcriptional RNA processing in greater detail in Chapters 8 and 9.

Although most well-defined genes are transcribed into mRNAs that encode proteins, some DNA sequences are transcribed into important functional RNAs that do not encode proteins [e.g., tRNAs and rRNAs, described in Chapters 5 and 9; miRNAs and siRNAs that regulate mRNA translation and stability, discussed in Chapter 9; and long noncoding RNAs (lncRNAs) that regulate transcription, discussed in Chapter 8]. Because the DNA sequences that encode these functional RNAs can cause specific phenotypes when they are mutated, these DNA regions also are generally referred to as *genes*, even though their final products are RNA molecules and not proteins.

In this section, we will examine the structure of genes in eukaryotes and how that structure influences gene expression and evolution. The nucleotide sequences within the chromosomal DNA of multicellular organisms can be classified on the basis of their functions and the number of times closely related sequences are found in the genomes of individuals of the same species, as shown in Table 7-1 and described in subsequent sections of the chapter.

TABLE 7-1 • Major Classes of Nuclear Eukaryotic DNA and Their Representation in the Human Genome

Class	Length	Copy Number in Human Genome	Fraction of Human

			Genome (%)[i]
Protein-coding genes	0.5–2200 kb	~19,000	~40[ii] (2.0[iii])
Long noncoding RNA genes	0.2–50 kb	~10,000	~15 (0.9[iii])
Tandemly repeated genes			
U2 snRNA	6.1 kb[iv]	~20	<0.0001
rRNAs	43 kb[iv]	~300	0.4
Repetitive DNA			
Simple-sequence DNA	1–500 bp	Variable	~6
Interspersed repeats (mobile DNA elements)			
DNA transposons	2–3 kb	300,000	3
LTR retrotransposons	6–11 kb	440,000	8
Non-LTR retrotransposons			
LINEs	6–8 kb	860,000	21
SINEs	100–400 bp	1,600,000	13
Processed pseudogenes	Variable	~12,500	~0.4
Intergenic regions	Variable	n.a.	~25

[i]The sum of "Fraction of the Human Genome (%)" totals more than 100% because mobile DNA elements are counted twice: once to show the different classes of human mobile DNA elements; and second as part of the intergenic regions and protein-coding genes where they are located in introns and 3′ untranslated regions of terminal exons.

[ii]Complete transcription units including exons and introns.

[iii]Total length of all exons. Protein-coding regions total 1.2 percent of the genome.

[iv]Length of each repeat in a tandemly repeated sequence.

SOURCE: Data from International Human Genome Sequencing Consortium, 2001, *Nature* **409**:860 and 2004, *Nature* **431**:931.

Most Genes of Multicellular Eukaryotes Contain Introns and Produce mRNAs Encoding Single Proteins

Many bacterial mRNAs (e.g., the mRNA encoded by the *trp* operon) include the coding region for several proteins that function together in a biological process. Such mRNAs are said to be *polycistronic*. (A *cistron* is a genetic unit encoding a single polypeptide.) In contrast, most eukaryotic mRNAs are *monocistronic*; that is, each mRNA molecule encodes a single protein. This difference between polycistronic mRNAs in bacteria and monocistronic mRNAs in eukaryotes correlates with a fundamental difference in their translation mechanisms. Within a bacterial polycistronic mRNA, a

ribosome-binding site is located near the start site for each of the protein-coding regions, or cistrons, in the mRNA. Translation initiation can begin at any of these multiple internal sites, producing alternative proteins from one polycistronic mRNA molecule. In most eukaryotic mRNAs, however, the 5′ cap directs ribosome binding, and translation begins at the closest AUG start codon to the 5′ cap. As a result, translation of most eukaryotic mRNAs begins only at this site, even if, as for many viral mRNAs, the mRNA molecule contains additional open reading frames beginning with an AUG initiation codon downstream from the first open reading frame that is used in that mRNA.

The term *primary transcript* refers to the initial RNA transcript from a gene before it is modified by RNA splicing or addition of a poly(A) tail. In many cases, the primary transcripts of eukaryotic protein-coding genes are processed into a single type of mRNA, which is translated to give a single type of polypeptide (see Figure 5-27). However, unlike bacterial and yeast genes, which generally lack introns, most genes in multicellular animals and plants contain introns, which are removed during RNA processing in the nucleus before the fully processed mRNA is exported to the cytosoplasm for translation. In many cases, the introns in a gene are considerably longer than the exons. The median intron length in human genes is 3.3 kb. However, some are much longer: the longest known human intron is 17,106 bp and lies within the *titin* gene, which encodes a very large structural protein in muscle cells (see Chapter 17). In

comparison, most exons in human genes contain only 50–200 bp. The typical human gene encoding an average-sized protein is about 50,000 bp long, but more than 95 percent of that sequence consists of introns and flanking noncoding 5′ and 3′ regions.

Many large proteins with required functions in multicellular organisms have repeated domains encoded by repeats of similar exons separated by introns of variable length. An example is fibronectin, a component of the extracellular matrix. The fibronectin gene contains multiple copies of five types of exons (see Figure 5-28). Such genes evolved by tandem duplication of the DNA encoding the repeated exon, probably by unequal crossing over during meiosis, as shown in Figure 7-2a.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 7-2 Exon and gene duplication. (a) Exon duplication often results from unequal crossing over during meiosis. Each parental chromosome (*top*) contains one ancestral gene containing three exons (blue) and two introns (orange). Homologous noncoding sequences called L1 long interspersed elements (red) lie 5′ and 3′ of the gene as well as in the intron between exons 2 and 3. As we will see later in the chapter, L1 elements have been repeatedly transposed to new sites in the genome over the course of human evolution, so that all chromosomes are peppered with them. The parental chromosomes are shown displaced relative to each other, so that a pair of the L1 elements are aligned. Homologous recombination between these L1 elements as shown would generate one recombinant chromosome in which the gene now has four exons (two copies of exon 3) and one chromosome in which the gene is missing exon 3. (b) The same process can generate duplications of entire genes. Each parental chromosome (*top*) contains one ancestral β-globin gene. After unequal recombination between L1 elements, subsequent independent mutations in the resulting duplicated genes could lead to slight changes in sequence that

might result in slightly different functional properties of the encoded proteins. Unequal crossing over can also result from rare recombinations between unrelated sequences. See D. H. A. Fitch et al., 1991, *Proc. Nat'l. Acad. Sci. USA* **88**:7396.

Simple and Complex Transcription Units Are Found in Eukaryotic Genomes

The cluster of genes that form a bacterial operon constitutes a single **transcription unit**, which is transcribed from a specific promoter in the DNA sequence to a termination site, producing a single primary transcript. As a consequence, genes and transcription units are often distinguishable in prokaryotes, since a single transcription unit contains several genes when they are part of an operon. In contrast, most eukaryotic genes are expressed from separate transcription units, so that each mRNA is translated into a single protein.

Eukaryotic transcription units are classified into two types — simple and complex — depending on the fate of the primary transcript, that is, the newly transcribed RNA before it is subjected to any modifications. A simple transcription unit contains the protein-encoding exons separated by introns, and upstream control regions (Figure 7-3a). The primary transcript produced from a *simple* transcription unit is processed to yield a single type of mRNA,

encoding a single protein (Figure 7-3a). In humans, simple transcription units, such as the one encoding β-globin, are rare. Approximately 95 percent of human transcription units are *complex*. Complex transcription units produce primary RNA transcripts that can be processed in more than one way, leading to formation of mRNAs containing different combinations of exons (see Figure 7-3b). Each alternative mRNA is translated into a single polypeptide, with translation usually initiating at the first AUG in the mRNA.

FIGURE 7-3 Simple and complex eukaryotic transcription units. (a) A simple transcription unit includes a region that encodes one protein, which extends from the $5'$ cap site to the $3'$ poly(A) site, plus the associated control regions. Exons (light blue rectangles) are separated by introns. Introns are removed during processing of the primary transcripts (dashed red lines); thus they do not occur in the functional monocistronic mRNA. (b) Complex transcription units produce primary transcripts that can be processed in alternative ways. (*Top*) If a primary transcript contains alternative splice sites, it can be processed into mRNAs with the same $5'$ and $3'$ exons but different internal exons. (*Middle*) If a primary transcript has two poly(A) sites, it can be processed into mRNAs with alternative $3'$ exons. (*Bottom*) If alternative promoters (*f* or *g*) are active in different cell types, mRNA_1, produced in a cell type in which *f* is activated, has a different first exon (1A) than mRNA_2, which is produced in a cell type in which *g* is activated (and in which exon 1B is used).

Multiple mRNAs can arise from one primary transcript in three ways. First, when a primary transcript contains **alternative splice sites**, the transcript can be processed into mRNAs with the same $5'$ and $3'$ exons but different internal exons (Figure 7-3b, *top*). Second, when a primary transcript has two poly(A) sites, the transcript can be processed into mRNAs with alternative $3'$ exons (Figure 7-3b,

middle). Third, alternative promoters may be present but active in different cell types (Figure 7-3b, *bottom*), For example, when promoter *f* is activated in cell type 1, then the first exon in $mRNA_1$ is exon 1A. In cell type 2, where promoter *f* is inactive but promoter *g* is activated, $mRNA_2$ begins with exon 1B.

It is common for one mRNA to be produced from a complex transcription unit in some cell types, while a different mRNA is made in other cell types. For example, the fibronectin gene (see Figure 5-28) encoding long, linear fibrous proteins is transcribed at high level in both fibroblasts, the major cell type in connective tissue, and hepatocytes, the principal liver cell type that secretes most of the extracellular proteins in blood. When expressed in fibroblasts, the fibronectin protein includes domains encoded by related exons EIIIA and EIIIB (green) that adhere to specific proteins anchored to the fibroblast cell surface. In contrast, when fibronectin is expressed in hepatocytes, the EIIIA and EIIIB exons are left out of the mRNA so that the hepatocyte isoform of fibronectin does not bind to cell surfaces and is free to circulate in the blood, where it can be incorporated into blood clots when they form through interactions with other fibronectin domains. This type of alternative mRNA splicing occurs for ~95 percent of human genes, greatly expanding the number of proteins encoded in the genomes of multicellular organisms.

Mutations in exons, introns, and transcription-control regions may influence expression of the protein encoded by a simple transcription unit. For example, in Figure 7-3a, mutation *a* or *b* in the transcription control region might reduce or prevent transcription from occurring, thus little or none of the encoded protein is synthesized. Mutation *c* within an exon could alter the amino acid sequence so that a stop codon is introduced or an abnormal protein is made. Finally, mutation *d* is located within an intron. If it introduces a new splice site, that will affect the sequence of the mRNA molecule, resulting in a nonfunctional protein.

In complex transcription units, the relationship between a mutation and a gene is not always straightforward. A mutation in the control region or in an exon shared by alternatively spliced mRNAs will affect all of the alternative proteins encoded by a given complex transcription unit. On the other hand, a mutation in an exon present in only one of the alternative mRNAs will affect only the protein encoded by that mRNA. Figure 7-3b shows examples of mutations in various components of a complex transcription unit.

As explained in Chapter 6, **genetic complementation** tests are commonly used to determine if two mutations are in the same or different genes (see Figure 6-7). However, in the complex transcription unit shown in Figure 7-3b (*middle*), mutations *d* and *e* would complement each other in a genetic complementation test even though they occur in the same gene, because a chromosome

with mutation *d* can express a normal protein encoded by $mRNA_2$ and a chromosome with mutation *e* can express a normal protein encoded by $mRNA_1$. Both mRNAs produced from this gene would be present in a diploid cell carrying both mutations, generating both protein products and hence a wild-type phenotype. However, a chromosome with mutation *c* in an exon common to both mRNAs would not complement either mutation *d* or mutation *e*. In other words, mutation *c* would be in the same complementation groups as mutations *d* and *e*, even though *d* and *e* themselves would not be in the same complementation group!

Given these complications with the genetic definition of a gene, the molecular definition outlined at the beginning of this section is commonly used. In the case of protein-coding genes, a gene is the DNA sequence transcribed into a pre-mRNA precursor, equivalent to a transcription unit, plus any regulatory elements required for synthesis of the primary transcript.

Protein-Coding Genes May Be Solitary or Belong to a Gene Family

The set of all human proteins is encoded by transcription units that comprise approximately 40 percent of the human genome. However, most of this sequence is in introns that average about 3.3 kb in length but vary greatly in size and can be up to ~17 kb. Compare this

with most human exons that are only 50–200 bp long. In multicellular organisms, roughly 25–50 percent of the protein-coding genes are represented only once in the haploid genome and thus are termed *solitary* genes. A well-studied example of a solitary protein-coding gene is the gene for lysozyme. Lysozyme is an enzyme that cleaves the polysaccharides in bacterial cell walls, causing the bacteria to lyse and die. It is abundant in chicken egg whites and is also found in human tears, where its activity helps to keep the egg and the surface of the eye sterile. The 15-kb DNA sequence encoding chicken lysozyme constitutes a simple transcription unit containing four exons and three introns. The flanking regions, extending about 20 kb upstream and downstream from the transcription unit, do not encode any detectable mRNAs and are thus examples of intergenic regions (i.e., DNA sequences between genes).

Duplicated genes constitute the second group of protein-coding genes. These genes have close but nonidentical sequences and are often located within 5–50 kb of one another. A set of duplicated genes that encodes proteins with similar but nonidentical amino acid sequences is called a **gene family**, and the encoded, closely related, homologous proteins constitute a **protein family**. A few protein families, such as protein kinases, vertebrate immunoglobulins, and olfactory receptors, include hundreds of members. Most protein families, however, include from a few to 30

or so members; common examples are cytoskeletal proteins, the myosin heavy chain, and the α-like and β-like globins in vertebrates.

The genes encoding the β-like globins are a good example of a gene family. As shown in Figure 7-4a, the β-like globin gene family contains five functional genes, designated *HBB* (encoding the most abundant adult β-globin), *HBD* (a minor adult β-globin), *HBG1* and *HBG2* (fetal β-globins), and *HBE1* (embryonic β-globin). Two identical β-like globin polypeptides combine with two identical α-like globin polypeptides (encoded by another gene family expressed during embryonic, fetal, and adult stages of development) and four heme prosthetic groups (see Figure 12-17) to form a hemoglobin molecule. All the hemoglobins formed from the different α-like and β-like globins carry oxygen in the blood, but they exhibit somewhat different properties that are suited to their specific functions in human physiology. For example, hemoglobins containing either the *HBG1*- or *HBG2*-encoded polypeptides are expressed only during fetal life. Because these fetal hemoglobins have a higher affinity for oxygen than adult hemoglobins, they can effectively extract oxygen from the maternal circulation in the placenta. The lower oxygen affinity of adult hemoglobins, which are expressed after birth, permits better release of oxygen to the tissues, especially muscles, which have a high demand for oxygen during exercise. The embryonic hemoglobin assembled from polypeptides encoded by the *HBE1* gene and the embryonic α-like globin gene *HBZ* has an

even higher affinity for oxygen than the fetal and adult hemoglobins.

FIGURE 7-4 Comparison of gene density in unicellular and multicellular eukaryotes. (Double black lines represent genomic DNA. Genes diagrammed above these lines are transcribed to the right; genes below are transcribed to the left.) (a) In this diagram of the β-globin gene cluster on human chromosome 11, the green vertical lines represent exons of β-globin–related genes. All of the human β-globin genes are transcribed to the left. The human β-globin gene cluster also contains a pseudogene (orange highlight) that is related to the functional β-globin genes but is not transcribed. Each red arrow indicates the location of an *Alu* sequence, a roughly 300-bp noncoding repeated sequence discussed in Section 7.3 that is abundant in the human genome. See F. S. Collins and S. M. Weissman, 1984, *Prog. Nucl. Acid Res. Mol. Biol.* **31**:315. (b) Diagram of genes in a randomly chosen 80 kb region of human chromosome 1. *RPF1* is transcribed to the right; *GNG5* and *CTBS* are transcribed to the left. Where the $3'$-exon is long enough, its $3'$ end is indicated by an arrowhead. (c) Diagram of yeast genes in an 80 kb region of chromosome III. The green boxes indicate open reading frames. Most of these are functional genes without introns. Note the much higher proportion of noncoding to coding sequences in the human DNA than in the yeast DNA. See S. G. Oliver et al., 1992, *Nature* **357**:28.

The different β-like globin genes arose by duplication of an ancestral gene, most likely as the result of unequal crossing over during meiotic recombination in a developing germ cell (egg or sperm) (see Figure 7-2b). Over evolutionary time, the two copies of the gene that resulted accumulated random mutations, resulting in *sequence drift*. Beneficial mutations that conferred some refinement in the basic oxygen-carrying function of hemoglobin were retained by natural selection. Repeated gene duplications and subsequent sequence drift and selection are thought to have generated the contemporary β-like globin genes observed in humans and other mammals today.

One region in the human β-like globin gene cluster contains a nonfunctional sequence, called a **pseudogene**, that is similar to the functional β-like globin genes (Figure 7-4a). Sequence analysis shows that this pseudogene has the same apparent exon–intron structure as the functional β-like globin genes, suggesting it arose by duplication of the same ancestral gene. However, there was little selective pressure to maintain the function of this gene. Consequently, sequence drift during evolution generated sequences that terminate translation and block mRNA processing, rendering this region nonfunctional. Because such pseudogenes are not deleterious, they remain in the genome and mark the location of a gene duplication that occurred in one of our ancestors, followed by sequence drift eliminating the gene function.

Duplications of segments of a chromosome (called *segmental duplication*) occurred fairly often during the evolution of multicellular plants and animals. As a result, a large fraction of the genes in these organisms today have been duplicated, allowing the process of sequence drift to generate gene families and pseudogenes. The extent of sequence divergence between duplicated copies of the genome and characterization of the homologous genomic sequences in related organisms allows us to estimate the time in evolutionary history when the duplication occurred. For example, the human fetal globin genes (*HBG1* and *HBG2*) evolved following the duplication of a 5.5-kb region in the β-globin locus that included the single *HBG*-globin gene in the common ancestor of catarrhine primates (Old World monkeys, apes, and humans) and platyrrhine primates (New World monkeys) about 50 million years ago.

Although members of gene families that arose relatively recently in evolution, such as the genes of the human β-globin family, are often found near one another on the same chromosome, members of gene families may also be found on different chromosomes in the same organism. This is the case for the human α-like globin genes, which were separated from the β-globin genes by an ancient chromosomal translocation. Both the α- and β-globin genes evolved from a single ancestral globin gene that was duplicated (see Figure 7-2b) to generate the predecessors of the contemporary α- and β-globin genes in mammals. Both the primordial α- and β-globin genes

then underwent further duplications to generate the different genes of the α- and β-globin gene clusters found in mammals today.

Several different gene families encode the various proteins that make up the cytoskeleton. These proteins are present in varying amounts in almost all cells. In vertebrates, the major cytoskeletal proteins are the actins, tubulins, and intermediate filament proteins such as the keratins, discussed in Chapters 17, 18, and 20. We examined the origin of one such family, the tubulin family, in Section 6.3. The keratins, important for determining the shape and physical properties of epithelial cells that cover tissue surfaces, have expanded into at least 54 functional genes in humans. Although the physiological rationale for the evolution of so many keratins is not as obvious as it is for the globins, the different members of the family probably have similar but subtly different functions suited to the particular type of cell in which they are expressed.

Heavily Used Gene Products Are Encoded by Multiple Copies of Genes

In vertebrates and invertebrates, the genes encoding ribosomal RNAs and some other nonprotein-coding RNAs, such as those involved in RNA splicing, occur as *tandemly repeated arrays*. Most often, copies of these sequences appear one after the other, in a head-to-tail fashion, over a long stretch of DNA. Within a tandem

array of rRNA genes, each copy is nearly exactly like all the others. Although the transcribed portions of the genes are the same, the nontranscribed regions between the transcribed regions can vary in length and sequence.

These tandemly repeated rRNA genes have evolved to meet the great cellular demand for their transcripts during cell replication. To understand why, consider that a fixed maximal number of rRNA molecules can be produced from a single gene during one cell generation when the gene is fully loaded with RNA polymerase molecules. If more RNA is required than can be transcribed from one gene, multiple copies of the gene are necessary. For example, during early embryonic development in humans, many embryonic cells have a doubling time of about 24 hours and contain 5–10 million ribosomes. To produce enough rRNA to form this many ribosomes, an embryonic human cell needs at least 100 copies of genes encoding the large and small rRNAs, and most of these genes must be close to maximally active for the cell to divide every 24 hours; that is, multiple RNA polymerases must be transcribing each rRNA gene at the same time. Indeed, all eukaryotes, including yeasts, contain 100 or more copies of the 5S rRNA gene as well as similar numbers of the genes encoding the other rRNAs.

The genes encoding tRNA and those encoding the histone proteins are also present in multiple copies in eukaryotic cells. As we will see later in this chapter, histones bind and organize nuclear DNA. Just as the cell requires multiple rRNA and tRNA genes to produce

sufficient numbers of ribosomes and tRNAs, multiple copies of the histone genes are required to produce sufficient histone protein to bind the large amount of nuclear DNA produced in each round of cell replication. While tRNA and histone genes often occur in clusters, they generally do not occur in tandem arrays in the human genome.

Nonprotein-Coding Genes Encode Functional RNAs

In addition to rRNA and tRNA genes, there are thousands of additional genes that are transcribed into nonprotein-coding RNAs, some with various known functions and many whose functions are not yet known. For example, **small nuclear RNAs (snRNAs)** function in RNA splicing, and **small nucleolar RNAs (snoRNAs)** function in rRNA processing and base modification in the nucleolus. The RNase P RNA is a ribozyme that functions in tRNA processing, and a large family (~19,000 in humans) of short **micro-RNAs (miRNAs)** regulates the translation and stability of specific mRNAs. The functions of these nonprotein-coding RNAs are discussed in Chapter 9. An RNA found in telomerase (see Figure 7-40) maintains the sequence at the ends of chromosomes, and the 7SL RNA is a component of the signal recognition particle that functions in the transport of secreted proteins and most membrane proteins into the endoplasmic reticulum (see Chapter 13). These and other nonprotein-coding

RNAs encoded in the human genome, and their functions when known, are listed in Table 7-2. Recent advances in DNA sequencing have led to the discovery of about 10,000 *long noncoding RNAs* (lncRNAs) in nuclei of mammalian cells. Some of these have been found to function in regulating the expression of specific protein-coding genes. Pursuing the functions of lncRNAs is currently a highly active area of research.

TABLE 7-2 • Known Nonprotein-Coding RNAs and Their Functions

RNA	Number of Genes in Human Genome	Function
rRNAs	~300	Protein synthesis
tRNAs	~500	Protein synthesis
snRNAs	~40	mRNA splicing
U7 snRNA	1	Histone mRNA $3'$ processing
snoRNAs	~85	Pre-rRNA processing and rRNA modification
miRNAs	~19,000	Regulation of gene expression
piRNAs	$>6 \times 10^7$	Suppress transposon transpositions in germ cells. Associated with PIWI proteins.
Xist	1	X-chromosome inactivation
7SK	1	Transcription control
RNase P RNA	1	tRNA $5'$ processing

7SL RNA	3	Protein secretion (component of signal recognition particle, SRP)
RNase MRP RNA	1	rRNA processing, mtDNA[i] replication
Telomerase RNA	1	Template for addition of telomeres
Vault RNAs	3	Components of Vault ribonucleoproteins (RNPs). Regulate autophagy.
hY1, hY3, hY4, hY5	~30	Components of ribonucleoproteins (RNPs), function unknown
H19	1	Unknown

KEY CONCEPTS OF SECTION 7.1

Eukaryotic Gene Structure and Organization

- In molecular terms, a gene is the entire DNA sequence required for synthesis of a functional protein or RNA molecule. In addition to the coding regions (exons), a gene includes control regions, and in multicellular animals and plants most genes include introns.
- A simple eukaryotic transcription unit produces a single monocistronic mRNA, which is translated into a single polypeptide.
- A complex eukaryotic transcription unit is transcribed into a primary transcript that can be processed into two or more different monocistronic mRNAs depending on the choice of splice sites or polyadenylation sites. A complex transcription unit with

alternative promoters generates two or more different mRNAs, often in different cell types (see Figure 7-3b).

- Many complex transcription units (e.g., the fibronectin gene) express one mRNA in one cell type and an alternative mRNA in a different cell type.
- About half the protein-coding genes in vertebrate genomic DNA are solitary genes, each occurring only once in the haploid genome. The remaining are duplicated genes, which arose by duplication of an ancestral gene and subsequent independent mutations (see Figure 7-2b). The proteins encoded by a gene family have homologous but nonidentical amino acid sequences and exhibit similar but slightly different properties that are optimal for the cell type in which they are expressed.
- In invertebrates and vertebrates, rRNAs are encoded by multiple copies of genes located in tandem arrays in genomic DNA. Multiple copies of tRNA, snRNA, and histone genes also occur, often in clusters, but not generally in tandem arrays in humans.
- Many genes also encode functional RNAs that are not translated into proteins but nonetheless perform significant functions, such as rRNA, tRNA, and snRNA. Among these are micro-RNAs, whose biological significance in regulating gene expression has most recently been appreciated. Understanding the function of many short non-coding RNAs and thousands of newly discovered nuclear long noncoding RNAs (lncRNAs) is currently an intense area of research.

7.2 Chromosomal Organization of Genes and Noncoding DNA

Having reviewed the relationship between transcription units and genes, we now consider the organization of genes on chromosomes and of noncoding DNA that is not expressed as coding sequences in exons of mRNAs or as stable functional RNAs such as tRNAs, miRNAs, and lncRNAs.

Genomes of Many Organisms Contain a Large Fraction of Noncoding DNA

Comparisons of the total chromosomal DNA per cell in various species first suggested that much of the DNA in certain organisms does not encode proteins or functional RNA or have any apparent regulatory function. For example, yeasts, fruit flies, chickens, and humans have successively more DNA in their haploid chromosome sets (11.9, 137, 1043, and 2968 Mb, respectively), in keeping with what we perceive to be the increasing complexity of these organisms. Yet the vertebrates with the greatest amount of DNA per cell are amphibians, which are surely less complex than humans in their structure and behavior. Even more surprising, the unicellular protozoan *Amoeba dubia* has 200 times more DNA per cell than humans. Many plant species also have considerably more DNA per cell than humans have. Tulips, for example, have 10 times as much

DNA per cell as humans. The DNA content per cell also varies considerably between closely related species. All insects or all amphibians would appear to be similarly complex, but the amount of haploid DNA in species within each of these phylogenetic classes varies by a factor of 100.

Sequencing and identification of exons in chromosomal DNA have provided direct evidence that the genomes of multicellular eukaryotes contain large amounts of noncoding DNA. For instance, only a small portion of the β-globin gene cluster of humans, which is about 80 kb long, encodes protein (see Figure 7-4a). Similarly, a randomly chosen 80-kb region from chromosome 1 includes only the nine short exons of the *RFP1* gene, the four exons of the *GNG5* gene, and the seven exons of the *CTBS* gene. The total length of sequence encoding mRNA in this 80-kb region is only 9325 base pairs, or ~12 percent. In contrast, a typical 80-kb stretch of DNA from the yeast *S. cerevisiae* contains many closely spaced protein-coding sequences, few introns, and little noncoding DNA (see Figure 7-4c).

The density of genes varies among regions of human chromosomal DNA, from *gene-rich* regions, where a few hundred base pairs separate transcription units, to large *gene deserts*, where intergenic regions are a few million base pairs long. Of the 96 percent of human genomic DNA that has been sequenced, only about 2.9 percent is exons, and only about 1.5 percent encodes proteins. (The

fraction of the genome that corresponds to exons is much larger than the fraction that encodes proteins because many protein-coding genes include exons for long 3′ untranslated regions and because there are many exons in nonprotein-coding lncRNAs; see Chapter 9.) We learned in the previous section that the intron sequences of most human genes are significantly longer than the exon sequences. Approximately 55 percent of human genomic DNA is thought to be transcribed into pre-mRNAs, pre-lncRNAs, or other nonprotein-coding RNAs in one cell type or another, but some 95 percent of this sequence is intronic and is thus removed by RNA splicing. The remaining 45 percent of human DNA constitutes noncoding DNA between genes (*intergenic regions*) as well as the regions of repeated DNA sequences that make up the centromeres and telomeres of the human chromosomes. Consequently, about 97 percent of human DNA does not encode proteins, functional noncoding RNAs, or potentially functional lncRNAs.

Different selective pressures may account, at least in part, for the remarkable difference in the amount of nonfunctional DNA in different organisms. For example, many microorganisms must compete with other species of microorganisms in the same environment for limited amounts of available nutrients, and metabolic economy is thus a critical characteristic for these organisms. Because synthesis of nonfunctional (i.e., noncoding) DNA requires time, nutrients, and energy, presumably there was selective pressure to lose nonfunctional DNA during the evolution of

rapidly growing microorganisms such as the yeast *S. cerevisiae*. On the other hand, natural selection in vertebrates depends largely on their behavior. The energy invested in DNA synthesis is trivial compared with the metabolic energy required for the movement of muscles and the function of the nervous system; thus there may have been little selective pressure on vertebrates to eliminate nonfunctional DNA. Furthermore, the replication time of cells in most vertebrates and plants is much longer than in rapidly growing microorganisms, so there may have been little selective pressure to eliminate nonfunctional DNA in order to permit rapid cellular replication.

Most Simple-Sequence DNAs Are Concentrated in Specific Chromosomal Locations

The most abundant class of nuclear DNA found in human cells is *repetitive DNA* (see Table 7-1). There are two types of repetitive DNA: simple-sequence DNA and interspersed repeats (also called *mobile DNA elements*). Interspersed repeats are discussed in Section 7.3. Here we discuss simple-sequence DNA.

Simple-sequence DNA or **satellite DNA**, which constitutes about 6 percent of the human genome, is composed of perfect or nearly perfect repeats of relatively short sequences. The length of each

repeat in simple-sequence DNA can range from 1 to 500 base pairs. DNA sequences in which the repeats each contain 1–13 bp are often called **microsatellites**. Most microsatellite DNA has a repeat length of 1–4 bp, and the repeats usually occur in tandem sequences of 150 repeats or fewer. Microsatellites are thought to have originated by *backward slippage* of a daughter strand on its template strand during DNA replication so that the same short sequence was copied twice (Figure 7-5). Also, for triplet repeats that are self-complementary and include a G (e.g., CAG), excision repair of an oxidized G, the most frequent type of spontaneous DNA damage in humans, can lead to displacement of a strand with the trinucleotide repeat. This displaced region can fold back into a hairpin that is incorporated into the repair patch. Further repair of the single-stranded loop by additional DNA repair enzymes results in an expansion of the number of repeats.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 7-5 Generation of microsatellite repeats by backward slippage of the nascent daughter strand during DNA replication. (a) Normal replication. Daughter strand is red and template strand is green. (b) If the nascent daughter strand "slips" backward relative to the template strand by one repeat, one new copy of the repeat is added to the daughter strand when DNA replication continues. An extra copy of the repeat forms a single-stranded loop in the daughter strand of the daughter duplex DNA molecule. (c) If this single-stranded loop is not removed by DNA repair proteins before the next round of DNA replication, the extra copy of the repeat is added to one of the double-stranded daughter DNA molecules.

Microsatellites occasionally occur within transcription units. Some individuals are born with a larger number of repeats in specific genes than is observed in the general population, presumably because of daughter-strand slippage during DNA replication or repair of DNA damage in a region of triplet repeats in the germ cells from which they and their forebears developed. Such expanded microsatellites have been found to cause at least 14 different types of neuromuscular diseases. In some cases, expanded microsatellites behave like a recessive mutation because they interfere only with the function or expression of the gene in which they occur. But more commonly, expanded microsatellites behave like dominant mutations. In *Huntington's disease*, triplet repeats occur within a coding region, resulting in the formation of long polymers of a single amino acid that may aggregate over time in long-lived neuronal cells, eventually interfering with normal cellular function. For example, expansion of a CAG repeat in the first exon of the gene involved in Huntington's disease leads to synthesis of long stretches of polyglutamine, which over several decades form

toxic aggregates resulting in neuronal cell death in patients with the disease.

Pathogenic expanded repeats can also occur in the noncoding regions of some genes, where they are thought to function as dominant mutations because they interfere with the processing of a subset of mRNAs in the muscle cells and neurons where the affected genes are expressed. For example, in patients with *myotonic dystrophy type 1*, transcripts of the *DMPK* gene contain between 50 and 1500 repeats of the sequence CUG in the 3′ untranslated region, compared with 5–34 repeats in unaffected individuals. The extended stretch of CUG repeats in affected individuals is thought to form a long RNA hairpin. This RNA molecule binds and sequesters nuclear RNA-binding proteins that normally regulate alternative RNA splicing of certain pre-mRNAs essential for muscle and nerve cell function. ■

As opposed to microsatellite DNA composed of repeats of 1 to 13 base pairs, *simple-sequence* DNA is composed of repeats of 14–500 bp in tandem arrays that are 20–100 kb long. In situ hybridization studies with metaphase chromosomes have localized much of the simple-sequence DNA to the centromeres, the discrete chromosomal regions that attach to spindle microtubules during mitosis and meiosis (Figure 7-6). Experiments in the fission yeast *S. pombe* indicate that these sequences are required to form a specialized chromatin structure called *centromeric heterochromatin*,

which is necessary for the proper segregation of chromosomes to daughter cells during mitosis. Simple-sequence DNA is also found in long tandem repeats at the ends of chromosomes, known as the telomeres. Here the repeat sequences prevent chromosome shortening during DNA replication, a topic we discuss further in Section 7.5.

EXPERIMENTAL FIGURE 7-6 Simple-sequence DNA is localized at the centromere in mouse chromosomes. Purified simple-sequence DNA from mouse cells was copied in vitro using *E. coli* DNA polymerase I and fluorescently labeled dNTPs to generate a fluorescently labeled DNA probe for mouse simple-sequence DNA. Chromosomes from cultured mouse cells were fixed and denatured on a microscope slide, and the chromosomal DNA was then hybridized in situ to the labeled probe (light blue). The slide was also stained with DAPI, a DNA-binding dye, to visualize the full length of the chromosomes (dark blue). Fluorescence microscopy shows that the simple-sequence probe hybridizes primarily to one end of the telocentric mouse chromosomes (i.e., chromosomes in which the centromeres are located at one end).

DNA Fingerprinting Depends on Differences in Length of Simple-Sequence DNAs

The nucleotide sequences of the repeat units in a simple-sequence DNA tandem array are highly conserved among individuals within a species. In contrast, the *number* of repeats, and thus the length of simple-sequence tandem arrays containing the same repeat unit, is quite variable among individuals. These differences in length are thought to result from unequal crossing over within regions of simple-sequence DNA during meiosis. As a consequence of this unequal crossing over, the lengths of some tandem arrays are unique in each individual.

In humans and other mammals, some simple-sequence DNA exists in relatively short 1–5-kb regions made up of 20–50 repeat units,

each containing 14–100 bp. These regions are called *minisatellites*, in contrast to microsatellites made up of 1–13-bp tandem repeats. Even slight differences in the total length of various minisatellites from different individuals can be detected by Southern blotting. This technique was exploited in the first application of *DNA fingerprinting*, which was developed to detect DNA *polymorphisms* (i.e., differences in sequence between individuals of the same species) (Figure 7-7).

FIGURE 7-7 Distinguishing individuals by DNA fingerprinting. (a) In this analysis of paternity, several minisatellite repeat lengths were determined by Southern blot analysis of restriction enzyme–digested genomic DNA and hybridization with a probe for a minisatellite sequence repeated at several different positions in the genome. This method generated hypervariable multiband patterns for each individual called "DNA fingerprints." Lane M shows the pattern of restriction fragment bands using the mother's DNA; C, using the child's

DNA; and F1 and F2 using DNA from two potential fathers. The child has minisatellite repeat lengths inherited from either the mother or F1, demonstrating that F1 is the father. Arrows indicate restriction fragments from F1, but not F2, found in the child's DNA. (b) In these DNA fingerprints of a specimen isolated from a victim and three people suspected of the crime, it is clear that minisatellite repeat lengths in the specimen match those of suspect 1. The victim's DNA was included in the analysis to ensure that the specimen DNA was not contaminated with DNA from the victim.

Today the far more sensitive polymerase chain reaction (PCR) technique (see Figure 6-18) is generally used in forensic genetic testing. Microsatellites consisting of 4-bp tandem repeats in 30–50 copies are usually analyzed today. The exact number of repeats at a specific location in the genome generally varies between the two homologous chromosomes of an individual (one inherited from the mother and one from the father) and between the Y chromosomes of different males. A mixture of pairs of PCR primers that hybridize to unique sequences flanking 13 of these short tandem repeats and a Y-chromosome short tandem repeat are used to amplify DNA in a sample from one individual. The resulting mixture of PCR product lengths is unique in the human population, except for identical twins. The use of PCR allows analysis of minute amounts of DNA, and individuals can be distinguished more precisely and reliably than by conventional fingerprinting.

Unclassified Intergenic DNA Occupies a Significant Portion of the Genome

About 45 percent of human DNA lies between transcription units. Much of this sequence is not repeated anywhere else in the genome. Enhancers on the order of 50–200 bp in length that help to regulate transcription at distant promoters occur in these long stretches of intergenic DNA, as well as in introns. These enhancers (discussed in Chapter 8) are often conserved during evolution, while the neighboring intergenic sequences are not conserved. Other conserved intergenic regions may perform significant functions that are not yet understood. For example, they may contribute to the structures of chromosomes discussed in Section 7.5.

KEY CONCEPTS OF SECTION 7.2

Chromosomal Organization of Genes and Noncoding DNA

- In the genomes of prokaryotes and most lower eukaryotes, which contain few nonfunctional sequences, coding regions are densely arrayed along the genomic DNA.
- Genomes of multicellular animals and plants contain many sequences that do not apparently code for functional RNAs or have any regulatory function. Much of this nonfunctional DNA is composed of repeated sequences.
- In humans, only about 2.9 percent of total DNA (the exons) actually encodes proteins or functional RNAs.
- Variation in the amount of nonfunctional DNA in the genomes of different species is largely responsible for the lack of a consistent relationship between the amount of DNA in the haploid chromosomes of an animal or plant and its phylogenetic complexity.
- Simple-sequence DNA, consisting of short sequences repeated in long tandem arrays, is preferentially located in centromeres and telomeres.
- The length of a particular simple-sequence tandem array is quite variable between individuals in a species, probably because of unequal crossing over during meiosis. Differences in the lengths of some simple-sequence tandem arrays form the basis for DNA fingerprinting (see Figure 7-7).

7.3 Transposable (Mobile) DNA Elements

The second type of repetitive DNA in eukaryotic genomes, **interspersed repeats**, is composed of a very large number of copies of relatively few sequence families (see Table 7-1). Also known as *moderately repeated DNA*, or *intermediate-repeat DNA*, these sequences are found throughout mammalian genomes and make up 25–50 percent of mammalian DNA (~45 percent of human DNA).

Because interspersed repeats have the unique ability to move within the genome, they are collectively referred to as **transposable DNA elements** or **mobile DNA elements** (we use these terms interchangeably). Barbara McClintock discovered the first mobile DNA elements while doing classical genetic experiments in maize (corn) during the 1940s. She characterized genetic entities that could move into and back out of genes, changing the phenotypes of corn kernels. Her theories were controversial until similar mobile elements were discovered in bacteria, where they were characterized as specific DNA sequences, and the molecular basis of their transposition was deciphered. Although transposable DNA elements were originally discovered in eukaryotes, they are also found in prokaryotes, although less frequently. Transposable DNA elements are essentially molecular symbionts that in most cases appear to have no specific function in the biology of their host

organisms, but exist only to maintain themselves. For this reason, Francis Crick referred to them as "selfish DNA."

The process by which these sequences are copied and inserted into a new site in the genome is called **transposition**. When transposition occurs in germ cells, the transposed sequences at their new sites are passed on to succeeding generations. In this way, mobile elements have accumulated in eukaryotic genomes over evolutionary time. Since mobile elements are eliminated very slowly from eukaryotic genomes, they now constitute a significant portion of the genomes of many eukaryotes.

Not only are mobile elements the source for much of the DNA in our genomes, but they also provide a mechanism for greatly increasing genome rearrangements by dispersing homologous sequences throughout the genome where meiotic recombination may occur (see Figure 7-2). Any one transposon transposes very rarely. However, since there are about 3.2 million transposons in the human genome (see Table 7-1), even with this very low frequency of transposition for each transposon (once in multiple generations), in humans there is about one new germ-line transposition for every eight individuals. Over time, transposon transpositions in germ cells have played an essential part in the evolution of genes that have multiple exons and of transcription-control regions that regulate transcription of genes in specific cell types and developmental periods (discussed in Chapter 8). In other words, although transposable elements probably evolved as molecular symbionts,

they have had an important function in the evolution of complex multicellular organisms. We will return to this topic at the end of this section.

Transposition also occurs within somatic cells. In this case, the transposed sequence is transmitted only to the daughter cells derived from that cell. In rare cases, somatic-cell transposition may lead to a mutation with detrimental phenotypic effects, such as the inactivation of a tumor-suppressor gene (see Chapter 25). In this section, we first describe the structure and transposition mechanisms of the major types of transposable DNA elements and then consider their likely role in evolution.

Movement of Mobile Elements Involves a DNA or an RNA Intermediate

The transposition of mobile elements occurs in two different ways: (1) transposition directly as DNA or (2) via an RNA intermediate transcribed from the mobile element by an RNA polymerase and then converted back into double-stranded DNA by a **reverse transcriptase** (Figure 7-8). Mobile elements that transpose directly as DNA are generally referred to as **DNA transposons**, or simply **transposons**. Eukaryotic DNA transposons excise themselves from one place in the genome, leaving that site and moving to another. Mobile elements that transpose to new sites in the genome via an

RNA intermediate are called **retrotransposons**. Retrotransposons make an RNA copy of themselves, convert that to double-stranded DNA, and introduce this new copy into another site in the genome, while also remaining at their original location. The movement of retrotransposons is analogous to the infectious process of retroviruses (see Figure 5-43). Indeed, retroviruses can be thought of as retrotransposons with genes encoding viral coats that allow them to transpose between cells. Retrotransposons can be further classified on the basis of their specific mechanism of transposition. To summarize, DNA transposons can be thought of as transposing by a cut-and-paste mechanism, while retrotransposons move by a copy-and-paste mechanism in which the copy is an RNA intermediate.

FIGURE 7-8 Two major classes of mobile elements. (a) Eukaryotic DNA transposons (orange) move via a DNA intermediate, which is excised from the donor site. (b) Retrotransposons (green) are first transcribed into an RNA molecule, which is then reverse-transcribed into double-stranded DNA. In both cases, the double-stranded DNA intermediate is integrated into the target-site DNA to complete movement. Thus DNA transposons move by a cut-and-paste mechanism, whereas retrotransposons move by a copy-and-paste mechanism.

Most Mobile Elements in Bacteria Are DNA Transposons Known as Insertion Sequences

Our first molecular understanding of mobile elements came from the study of *Escherichia coli* mutations caused by the insertion of a 1–2-kb DNA sequence into the middle of a gene. The inserted DNA is called an *insertion sequence*, or *IS element*. More than 1000 different IS elements have been found in *E. coli* and other bacteria.

Transposition of a bacterial IS element is a rare event, occurring in only one in 10^5–10^7 cells per generation. Since only a small fraction of bacterial DNA is noncoding or comprises promoters and operators involved in transcription control, when a transposition occurs in a bacterial cell, it may inactivate an essential gene, killing the host cell and the IS elements it carries. Consequently, the low rate of transposition of IS elements in bacteria may have evolved because higher rates of transposition would probably result in too great a mutation rate for the host species to survive. However, since IS elements transpose more or less randomly, some transposed sequences insert into nonessential regions of the host genome (e.g., regions between genes), allowing the host cell to survive. In this way, the number of transposons in a strain of a bacteria reaches an equilibrium at a relatively low number (usually less than 20). IS elements can also insert themselves into plasmids or lysogenic

viruses and can thus be transferred to other cells. In this way, IS elements can transpose into the chromosomes of new host cells.

The general structure of an IS element is diagrammed in Figure 7-9. An inverted repeat of 10–40 bp is invariably present at each end of an IS element. In an *inverted repeat*, the $5' \rightarrow 3'$ sequence on one strand is repeated on the other strand, such as

$$\begin{array}{l} \longrightarrow \\ 5'\ \mathbf{GAGC}\text{———}\mathbf{GCTC}\ 3' \\ 3'\ \mathbf{CTCG}\text{———}\mathbf{CGAG}\ 5' \\ \qquad\qquad\qquad \longleftarrow \end{array}$$

FIGURE 7-9 General structure of bacterial IS elements. The relatively large central region of an IS element, which encodes one or two enzymes required for transposition, is flanked by an inverted repeat at each end. The sequences of the inverted repeats are represented by the red regions, with white arrows indicating the direction of the sequence from $5'$ to $3'$. They are nearly identical, but are oriented in opposite directions. The sequence of the inverted repeat is characteristic of a particular type of IS element. The $5'$ and $3'$ short *direct repeats* (as opposed to the *inverted repeats*) are represented by black regions with a white arrow indicating the direction of the sequence $5'$ to $3'$). These short direct repeats are not transposed with the insertion element; rather, they are insertion-site sequences that become duplicated, with one copy at each end, during insertion of a mobile element. The length of the direct repeats is constant for a given IS element, but their sequence depends

on the site of insertion and therefore varies with each transposition of the IS element. The regions in this diagram are not to scale; the coding region makes up most of the length of an IS element.

Between the inverted repeats in an IS element is a region that encodes a *transposase*, an enzyme required for transposition of the IS element to a new site. The transposase is rarely expressed, accounting for the low frequency of transposition. A hallmark of IS elements is the presence of a 5–11-bp *direct repeat* sequence immediately adjacent to the ends of the inserted element. The *length* of the direct repeat is characteristic of each type of IS element, but its *sequence* depends on the target site where a particular copy of the IS element inserted. When the sequence of a mutated gene containing an IS element is compared with the wild-type gene sequence, only one copy of the direct repeat is found in the wild-type gene. Duplication of this target-site sequence to create the second direct repeat adjacent to an IS element occurs during the insertion process.

As depicted in Figure 7-10, transposition of an IS element occurs by a cut-and-paste mechanism. Transposase performs three functions in this process: it (1) precisely excises the IS element from the donor DNA (Figure 7-10, step **1**), (2) makes staggered cuts in a short sequence in the target DNA (Figure 7-10, step **1**), and (3) ligates the 3′ termini of the IS element to the 5′ ends of the cut donor DNA (Figure 7-10, step **2**). Finally, a host-cell DNA polymerase fills in the

single-stranded gaps, generating the short direct repeats that flank IS elements, and DNA ligase joins the free ends (Figure 7-10, step 3).

FIGURE 7-10 Model for transposition of bacterial insertion sequences. Step **1**: Transposase, which is encoded by the IS element (IS*10* in this example), cleaves both strands of the donor DNA containing the IS element (*top left*) next to the inverted repeats (dark red, see Figure 7-9 where the inverted repeats are also diagrammed in dark red), excising the IS*10* element. At a largely random target site, transposase makes staggered cuts in the target DNA (*top right*). In the case of IS*10*, the two cuts are 9 bp apart. Thin red vertical arrows indicate the phosphodiester bonds cut by the transposase. Step **2**: Ligation of the $3'$ ends of the excised IS element to the $5'$ ends in target site DNA left by the staggered cut in the target DNA is also catalyzed by transposase. Step **3**: The 9-bp gaps of single-stranded DNA left in the resulting intermediate are filled in by a cellular DNA polymerase. Finally, cellular DNA ligase forms the $3' \rightarrow 5'$ phosphodiester bonds between the $3'$ ends of the extended target DNA strands and the $5'$ ends of the IS*10* strands. This process results in duplication of the target-site sequence on each side of the inserted IS element. Note that the lengths of the target site and IS*10* are not to scale. See H. W. Benjamin and N. Kleckner, 1989, *Cell* **59**:373; and 1992, *Proc. Nat'l. Acad. Sci. USA* **89**:4648.

Eukaryotic DNA Transposons Move Using a Cut-and-Paste Process

McClintock's original discovery of mobile elements came from her observation of spontaneous mutations in maize that affect the production of enzymes required to make anthocyanin, a purple pigment in maize kernels. Mutant kernels are white and wild-type kernels are purple. One class of these mutations is revertible at high

frequency, whereas a second class does not revert unless the mutations occur in the presence of the first class of mutations. McClintock called the agents responsible for the first class of mutations *activator (Ac) elements* and those responsible for the second class *dissociation (Ds) elements* because they also tended to be associated with chromosome breaks.

Many years after McClintock's pioneering discoveries, cloning and sequencing revealed that Ac elements are equivalent to bacterial IS elements. Like IS elements, they contain inverted terminal repeat sequences that flank a region encoding a transposase, which recognizes the terminal repeats and catalyzes transposition to a new site in the host DNA. Ds elements are deleted forms of Ac elements in which a portion of the sequence encoding transposase is missing. Because it does not encode a functional transposase, a Ds element cannot move by itself. However, in plants that carry Ac elements and thus express a functional transposase, Ds elements can be transposed because they retain the inverted terminal repeats recognized by the transposase.

Since McClintock's early work on mobile elements in corn, DNA transposons have been identified in other eukaryotes. For instance, *Drosophila* possess a DNA transposon known as a *P element*, which moves by a mechanism similar to that used by bacterial insertion sequences. Current methods for constructing transgenic *Drosophila* depend on engineered, high-level expression of the P-element

transposase and use of the P-element inverted terminal repeats as targets for transposition.

DNA transposition by the cut-and-paste mechanism can result in an increase in the copy number of a transposon if it occurs during S phase of the cell cycle (see Figure 1-22), when DNA synthesis occurs. Transposon copy number increases when the donor DNA is in one of the two daughter DNA molecules in a region of a chromosome that has replicated but the target DNA is in a region that has not yet replicated. When DNA replication is complete at the end of S phase, the transposon DNA in its new location has also been replicated, resulting in a net increase in the total number of transposon copies in the cell (Figure 7-11). When such a transposition occurs during S phase preceding meiosis, one of the four germ cells produced contains the extra copy of the transposon. Repetition of this process over evolutionary time has resulted in the accumulation of large numbers of DNA transposons in the genomes of some organisms. Human DNA contains about 300,000 copies of full-length and deleted DNA transposons, amounting to about 3 percent of human DNA. As we will see shortly, this mechanism can lead to the transposition of genomic DNA as well as the transposon itself.

FIGURE 7-11 Mechanism for increasing DNA-transposon copy number. If a DNA transposon, which transposes by a cut-and-paste mechanism (see Figure 7-10), transposes during S phase from a region of the chromosome that has replicated to a region that has not yet replicated, then when chromosomal replication is completed, one of the two daughter chromosomes will have a net increase of one copy of the transposon.

LTR Retrotransposons Behave Like Intracellular Retroviruses

The genomes of all eukaryotes studied, from yeast to humans, contain retrotransposons, mobile DNA elements that transpose through an RNA intermediate using a reverse transcriptase (see Figure 7-8b). These mobile elements are divided into two major categories: those containing and those lacking **long terminal repeats (LTRs)**. LTR retrotransposons, which we discuss here, are common in yeast (e.g., Ty elements) and in *Drosophila* (e.g., *copia* elements). In humans, LTR retrotransposons constitute about 8 percent of the genomic DNA. Non-LTR retrotransposons are the most common type of mobile element in mammals; these retrotransposons are described in the next section.

The general structure of LTR retrotransposons found in eukaryotes is depicted in Figure 7-12. In addition to the short direct repeats that are typical of all transposons, these retrotransposons are marked by the presence of LTRs flanking the central protein-coding region. The LTRs in LTR retrotransposons are 250–600 bp long. Unlike the inverted repeats that flank IS elements and DNA transposons, LTRs are *direct* repeats.

FIGURE 7-12 General structure of eukaryotic LTR retrotransposons. The central protein-coding region is flanked by two long terminal repeats (LTRs), which are element-specific direct repeats. Like other mobile elements, integrated retrotransposons have short target-site direct repeats at each end. Note that the different regions are not drawn to scale. The protein-coding region constitutes 80 percent or more of a retrotransposon and encodes reverse transcriptase, integrase, and other proteins required for transposition.

LTR retrotransposons and infectious retroviruses have much in common. The LTRs in retrotransposons are characteristic of integrated retroviral DNA and are critical to the life cycle of retroviruses and retrotransposons. In addition to sharing LTRs with retroviruses, LTR retrotransposons encode all the proteins of the most common type of retroviruses, except for the envelope proteins. Lacking these envelope proteins, LTR retrotransposons cannot bud from their host cell and infect other cells; however, they can transpose to new sites in the DNA of their host cell. Because of their clear relationship with retroviruses, LTR retrotransposons are often called *retrovirus-like elements*.

A key step in the retroviral life cycle is the formation of retroviral genomic RNA from integrated retroviral DNA (see Figure 5-43). We describe this process in some detail here because it serves as a model for the generation of the RNA intermediate during the transposition of LTR retrotransposons. As depicted in Figure 7-13, the leftward retroviral LTR functions as a promoter that directs host-cell RNA polymerase to initiate transcription at the 5′ nucleotide of the roughly 20-base R sequence that is repeated at each end of the

retroviral RNA. After the entire downstream retroviral DNA has been transcribed, the RNA sequence corresponding to the rightward LTR directs host-cell RNA-processing enzymes to cleave the primary transcript and add a poly(A) tail at the 3′ end of the R sequence. The resulting retroviral RNA genome, which lacks a complete LTR, exits the nucleus and is packaged into a virion that buds from the host cell.

FIGURE 7-13 Generation of retroviral genomic RNA from integrated retroviral DNA. The left LTR of the integrated provirus DNA functions as a promoter, and the right LTR sequence functions as a poly(A) site. (See text.) R represents an ~20 base sequence that is precisely repeated at each end of the viral genomic RNA (bottom). U5 and U3 refer to sequences immediately adjacent to the R sequence at the 5′- and 3′-ends of the genomic RNA, respectively. While U5 and U3 become repeated in the sequence of the integrated provirus DNA (see Figure 7-14), they are not repeated in the genomic retroviral RNA (hence the names

U5 and U3 where “U” indicates a unique sequence in the viral RNA). Short direct repeat sequences (black) flanking the integrated provirus are generated during integration of the retroviral DNA into the host-cell genome. A similar mechanism is thought to generate the RNA intermediate during transposition of LTR retrotransposons.

After a retrovirus infects a cell, reverse transcription of its RNA genome by the retrovirus-encoded reverse transcriptase yields a double-stranded DNA containing complete LTRs (Figure 7-14). This DNA synthesis takes place in the cytosol. The double-stranded DNA, with an LTR at each end, is then transported into the nucleus in a complex with integrase, another enzyme encoded by retroviruses and retrotransposons. Retroviral integrases are closely related to the transposases encoded by DNA transposons and use a similar mechanism to insert the double-stranded retroviral DNA into the host-cell genome (see Figure 7-10), generating short direct repeats of the target-site sequence at either end of the inserted viral DNA sequence. This complex mechanism of reverse transcription is a critical aspect of the retrovirus life cycle because it generates the complete 5′ LTR that functions as a promoter for initiation of transcription precisely at the 5′ nucleotide of the R sequence (Figure 7-13), and the complete 3′ LTR that functions as a poly(A) site leading to polyadenylation precisely at the 3′ nucleotide of the R sequence. Consequently, no nucleotides are lost from an LTR retrotransposon as it undergoes successive rounds of insertion, transcription, reverse transcription, and reinsertion at a new site.

FIGURE 7-14 Model for reverse transcription of retroviral genomic RNA into DNA. (Figure caption is on the facing page.) In this model, a complicated series of nine events generates a

double-stranded DNA copy of the single-stranded RNA genome of a retrovirus. The genomic RNA is packaged in the virion with a retrovirus-specific cellular tRNA hybridized to a complementary sequence near its $5'$ end, called the *primer-binding site* (PBS). The retroviral RNA has a short direct repeat terminal sequence (R) at each end. The overall reaction is carried out by reverse transcriptase, which catalyzes polymerization of deoxyribonucleotides. RNase H, also encoded in the viral RNA and packaged into the virion particle, digests the RNA strand in a DNA-RNA hybrid. The entire process yields a double-stranded DNA molecule that is longer than the template RNA and has a long terminal repeat (LTR) at each end. The different regions are not shown to scale. The PBS and R regions are actually much shorter than the U5 and U3 regions, and the central coding region is very much longer than the other regions. See E. Gilboa et al., 1979, *Cell* **18**:93.

As noted above, LTR retrotransposons encode reverse transcriptase and integrase. By analogy with retroviruses, these mobile elements move by a copy-and-paste mechanism whereby reverse transcriptase converts an RNA copy of a donor element into DNA, which is inserted into a target site by integrase. The experiments depicted in Figure 7-15 provided strong evidence for the role of an RNA intermediate in the transposition of Ty LTR retrotransposons in yeast. When yeast cells are transformed with a Ty-containing plasmid, the Ty element can transpose to new sites, although normally this occurs at a low rate. Using the elements diagrammed at the top of the figure, researchers engineered two different recombinant plasmid vectors containing recombinant Ty elements adjacent to a strong galactose-activated promoter. Yeast cells transformed with these plasmids were grown in a galactose-containing medium to induce transcription of the Ty element, or in a galactose-free medium where Ty transcription is not induced. In experiment 1, growth of cells in galactose-containing medium

resulted in many more transpositions than in galactose-free medium, indicating that transcription into an mRNA intermediate is required for Ty transposition. In experiment 2, an intron from an unrelated yeast gene was inserted into the putative protein-coding region of the recombinant galactose-responsive Ty element. This intron sequence was lost from Ty elements transposed to new sites. This absence of the intron in transposed Ty elements was strong evidence that transposition involves an mRNA intermediate from which the intron was removed by RNA splicing, as depicted in the box on the right. In contrast, eukaryotic DNA transposons, such as the Ac element of maize, contain introns within the transposase gene, indicating that they do not transpose via an RNA intermediate.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 7-15 The yeast Ty element transposes through an RNA intermediate. Ty transcription from a plasmid was experimentally manipulated by fusing the Ty element to a *GAL1* transcription control region. When transcription was increased by culturing the cells in medium with galactose (experiment 1), the frequency of Ty transposition was greatly increased. When an intron from another yeast gene was inserted into the middle of the Ty sequence in this plasmid (experiment 2), addition of galactose to the media stimulated transposition of Ty elements lacking the intron. This indicates that transposition likely involves an RNA intermediate from which the intron was removed by RNA splicing, as depicted in the box on the right. See J. Boeke et al., 1985, *Cell* **40**:491.

The most common LTR retrotransposons in humans are called *ERVs*, for *e*ndogenous *r*etro*v*iruses. Most of the 443,000 ERV-related DNA sequences in the human genome consist only of isolated LTRs. These sequences are derived from full-length proviral DNA by

homologous recombination between two LTRs, resulting in deletion of the internal retroviral sequences. Isolated LTRs such as these cannot be transposed to a new position in the genome, but recombination between homologous LTRs at different positions in the genome has probably contributed to the chromosomal DNA rearrangements leading to gene and exon duplications, the evolution of proteins with new combinations of exons, and, as we will see in Chapter 8, the evolution of complex control of gene expression.

Non-LTR Retrotransposons Transpose by a Distinct Mechanism

The most abundant mobile elements in mammals are retrotransposons that lack LTRs, sometimes called *nonviral retrotransposons*. These moderately repeated DNA sequences form two classes in mammalian genomes: **long interspersed elements (LINEs)** and **short interspersed elements (SINEs)**. In humans, full-length LINEs are about 6 kb long, and SINEs are about 300 bp long (see Table 7-1). Repeated sequences with the characteristics of LINEs have been observed in protozoans, insects, and plants, but for unknown reasons, they are particularly abundant in the genomes of mammals. SINEs too are found primarily in mammalian DNA. Large numbers of LINEs and SINEs have accumulated in mammalian genomes over evolutionary time by repeated copying of sequences

at a few positions in the genome and insertion of the copies into new positions.

LINEs

Human DNA contains three major families of LINEs, L1, L2, and L3, that are similar in their mechanism of transposition but differ in their sequences. Only members of the L1 family transpose in the contemporary human genome; apparently there are no remaining functional copies of L2 or L3 to provide the proteins required for their transposition. LINE sequences are present at roughly 900,000 sites in the human genome, accounting for a staggering 21 percent of total human DNA. The general structure of a complete LINE is diagrammed in Figure 7-16. LINEs are usually flanked by short direct repeats, the hallmark of mobile elements, and contain two long open reading frames (ORFs, which are protein-coding regions; see Section 6.3). ORF1, about 1 kb long, encodes an RNA-binding protein. ORF2, about 4 kb long, encodes a protein that has a long region of homology with the reverse transcriptases of retroviruses and LTR retrotransposons, but also exhibits DNA endonuclease activity.

FIGURE 7-16 General structure of a LINE. The length of the target-site direct repeats varies among the copies of a LINE at different sites in the genome. Although the full-length LINE element is about 6 kb long, variable amounts of the left end are absent at over 90 percent of the sites where this mobile element is found. The shorter open reading frame (ORF1), about 1 kb in length, encodes an RNA-binding protein. The longer ORF2, about 4 kb in length, encodes a bifunctional protein with reverse transcriptase and DNA endonuclease activity. Note that LINEs lack the long terminal repeats found in LTR retrotransposons.

Evidence for the mobility of L1 elements first came from analysis of DNA cloned from patients with certain genetic diseases such as hemophilia and myotonic dystrophy. DNA from these patients was found to carry mutations resulting from insertion of an L1 element into a gene, whereas no such element occurred within that gene in either parent. About 1 in 600 mutations that cause significant disease in humans are due to L1 transpositions or SINE transpositions that are catalyzed by L1-encoded proteins. Later experiments similar to those just described with yeast Ty elements (see Figure 7-15) confirmed that L1 elements transpose through an RNA intermediate. In these experiments, an intron was introduced into a cloned mouse L1 element and the recombinant L1 element was stably transfected into cultured hamster cells. After several cell doublings, a DNA fragment corresponding to the L1 element but

lacking the inserted intron was detected in the cells. This finding strongly suggests that, over time, the recombinant L1 element containing the inserted intron had transposed to new sites in the hamster genome through an RNA intermediate that underwent RNA splicing to remove the intron. ■

Since LINEs do not contain LTRs, their mechanism of transposition through an RNA intermediate differs from that of LTR retrotransposons. In vitro studies indicate that transcription by RNA polymerase is directed by promoter sequences at the left end of integrated LINE DNA. LINE RNA is polyadenylated by the same post-transcriptional mechanism that polyadenylates other mRNAs. The LINE RNA is then exported into the cytosol, where it is translated into ORF1 and ORF2 proteins. Multiple copies of ORF1 protein bind to the LINE RNA, and ORF2 protein binds to the poly(A) tail. The LINE RNA is then transported back into the nucleus as a complex with ORF1 and ORF2 proteins, where it is reverse-transcribed into LINE DNA by ORF2. The mechanism involves staggered cleavage of cellular DNA at the insertion site, followed by priming of reverse transcription by the resulting cleaved cellular DNA, as detailed in Figure 7-17. The complete process results in insertion of a copy of the original LINE retrotransposon into a new site in chromosomal DNA. A short direct repeat is generated at the insertion site because of the initial staggered cleavage of the two chromosomal DNA strands.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and

FIGURE 7-17 Proposed mechanism of LINE reverse transcription and integration. Only ORF2 protein is represented here. Newly synthesized LINE DNA is shown in black. ORF1 and ORF2 proteins, produced by translation of LINE RNA in the cytoplasm, bind to LINE RNA and transport it into the nucleus. Step **1**: In the nucleus, ORF2 makes staggered cuts in AT-rich target-site DNA, generating the DNA $3'$-OH ends indicated by blue arrowheads. Step **2**: The $3'$ end of the T-rich DNA strand hybridizes to the poly(A) tail of the LINE RNA and primes DNA synthesis by ORF2. Step **3**: ORF2 extends the DNA strand using the LINE RNA as a template. Steps **4** and **5**: When synthesis of the LINE DNA bottom strand reaches the $5'$ end of the LINE RNA template, ORF2 extends the newly synthesized LINE DNA using as a template the top-strand cellular DNA generated by the initial ORF2 staggered cleavage. Step **6**: A cellular DNA polymerase extends the $3'$ end of the top strand generated by the initial ORF2 staggered cut, using the newly synthesized bottom-strand LINE DNA as a template. The LINE RNA is digested as the DNA polymerase extends the upper-strand DNA (this also occurs during removal of lagging-strand primer RNA during cellular DNA synthesis; see Figure 5-11). The $3'$ ends of the newly synthesized DNA strands are ligated to the $5'$ ends of the cellular DNA strands as in lagging-strand cellular DNA synthesis. See D. D. Luan et al., 1993, *Cell* **72**:595.

As noted already, the DNA form of an LTR retrotransposon is synthesized from its RNA form in the cytosol using a cellular tRNA as a primer for reverse transcription of the first strand of DNA (see Figure 7-14). The resulting double-stranded DNA with long terminal repeats is then transported into the nucleus, where it is integrated into chromosomal DNA by a retrotransposon-encoded integrase. In contrast, the DNA form of a non-LTR retrotransposon is synthesized in the nucleus. The synthesis of the first strand of the non-LTR retroviral DNA by ORF2, a reverse transcriptase, is primed by the $3'$ end of cleaved chromosomal DNA, which base-pairs with the poly(A) tail of the non-LTR RNA (Figure 7-17, step **1**). Since its synthesis is primed by the cut end of a cleaved chromosome, and since synthesis

of the other strand of the non-LTR retrotransposon DNA is primed by the 3′ end of chromosomal DNA on the other side of the initial cut (step **6**), the mechanism of synthesis results in integration of the non-LTR retrotransposon DNA. There is no need for an integrase to insert the non-LTR retrotransposon DNA. Because its synthesis begins with reverse transcription of a poly(A) tail on the LINE RNA, one end of a non-LTR retrotransposon is AT-rich.

The vast majority of LINEs in the human genome are truncated at their 5′ end, suggesting that reverse transcription was terminated before completion and that the resulting fragments, extending variable distances from the poly(A) tail, were inserted. Because of this shortening, the average size of LINE elements is only about 900 bp, even though the full-length sequence is about 6 kb long. Truncated LINE elements, once formed, probably are not further transposed because they lack a promoter for transcription of the RNA intermediate. In addition to the fact that most L1 insertions are truncated, nearly all the full-length elements contain stop codons and frameshift mutations in ORF1 and ORF2; these mutations have probably accumulated in most LINE sequences over evolutionary time. As a result, only about 0.01 percent of the LINE sequences in the human genome, or about 60 in total number, are full-length, with intact open reading frames for ORF1 and ORF2.

SINEs

The most abundant class of mobile elements in the human genome, SINEs constitute about 13 percent of total human DNA. Varying in length from about 100 to 400 base pairs, these retrotransposons do not encode protein, but most contain a 3′ AT-rich sequence similar to that in LINEs. SINEs are transcribed by RNA polymerase III, the same nuclear RNA polymerase that transcribes genes encoding tRNAs, 5S rRNAs, and other small stable RNAs. Most likely, the ORF1 and ORF2 proteins expressed from full-length LINEs mediate reverse transcription and integration of SINEs by the mechanism depicted in Figure 7-17. Consequently, SINEs can be viewed as parasites of the LINE symbionts, competing with LINE RNAs for binding, reverse transcription, and integration by LINE-encoded ORF1 and ORF2.

SINEs occur at about 1.6 million sites in the human genome. Of these, about 1.1 million are *Alu elements*, so named because they contain a single recognition site for the restriction enzyme *Alu*I. *Alu* elements exhibit considerable sequence homology with, and probably evolved from, 7SL RNA, a cytosolic RNA in a ribonucleoprotein complex called the signal recognition particle. This abundant cytosolic ribonucleoprotein particle aids in targeting certain polypeptides to the membranes of the endoplasmic reticulum (see Chapter 13). *Alu* elements are scattered throughout the human genome at sites where their insertion has not disrupted gene expression: between genes, within introns, and in 3′ untranslated regions. For instance, nine *Alu* elements are located

within the 80-kb human β-globin gene cluster (see Figure 7-4a). Of the new germ-line non-LTR retrotranspositions that are estimated to occur about once in every eight individuals, about 40 percent involve L1 elements and 60 percent involve SINEs, of which about 90 percent of the latter are *Alu* elements. Like other mobile elements, most SINEs have accumulated mutations from the time of their insertion in the germ line of an ancient ancestor of modern humans. Like LINEs, many SINEs are truncated at their 5′ ends.

Other Retroposed RNAs Are Found in Genomic DNA

In addition to the mobile elements listed in Table 7-1, DNA copies of a wide variety of mRNAs appear to have become integrated into chromosomal DNA. Since these sequences lack introns and do not have flanking sequences similar to those of functional gene copies, they clearly are not simply duplicated genes that have drifted into nonfunctionality and become pseudogenes, as discussed earlier (see Figure 7-4a). Instead, these DNA segments appear to be retrotransposed copies of spliced and polyadenylated mRNA. Compared with normal genes encoding mRNAs, these inserted segments generally contain multiple mutations, which are thought to have accumulated since they were first reverse-transcribed and randomly integrated into the genome of a germ cell in an ancient ancestor. These nonfunctional genomic copies of mRNAs are

referred to as *processed pseudogenes*. Most processed pseudogenes are flanked by short direct repeats, supporting the hypothesis that they were generated by rare retrotransposition events involving cellular mRNAs.

Other interspersed repeats representing partial or mutant copies of genes encoding small nuclear RNAs (snRNAs) and tRNAs are found in mammalian genomes. Like processed pseudogenes derived from mRNAs, these nonfunctional copies of small RNA genes are flanked by short direct repeats and most likely result from rare retrotransposition events that have accumulated through the course of evolution. Enzymes expressed from a LINE are thought to have carried out these retrotransposition events involving mRNAs, snRNAs, and tRNAs.

Mobile DNA Elements Have Significantly Influenced Evolution

Although most mobile DNA elements appear to have no direct function other than to maintain their own existence, their presence has had a profound effect on the evolution of modern-day organisms. About half the spontaneous mutations in *Drosophila* result from insertion of a mobile DNA element into or near a transcription unit. In mammals, mobile elements cause a much smaller proportion of spontaneous mutations: about 10 percent in

mice and 0.1–0.2 percent in humans. Still, mobile elements have been found in mutant alleles associated with several human genetic diseases. For example, insertions into the clotting factor IX gene cause hemophilia, and insertions into the gene encoding the muscle protein dystrophin lead to Duchenne muscular dystrophy. The genes encoding clotting factor IX and dystrophin are both on the X chromosome. Consequently, disease resulting from a transposition into these genes occurs primarily in males, in which there is no second copy of the normal gene to complement the resulting mutation.

In lineages leading to multicellular eukaryotes, homologous recombination between mobile DNA elements dispersed throughout ancestral genomes may have generated gene duplications and other DNA rearrangements during evolution (see Figure 7-2b). For instance, cloning and sequencing of the β-globin gene clusters from various primate species has provided strong evidence that the human *HGB1* and *HGB2* genes encoding fetal β-globins arose from an unequal homologous crossover between two L1 elements flanking an ancestral globin gene. Subsequent divergence of the duplicated genes led to the acquisition of distinct, beneficial functions by each duplicated gene. Unequal crossing over between mobile elements located within introns of a particular gene could lead to the duplication of exons within that gene (see Figure 7-2a). This process most likely influenced the evolution of genes that

contain multiple copies of similar exons encoding similar protein domains, such as the fibronectin gene (see Figure 5-28).

Some evidence suggests that during the evolution of multicellular eukaryotes, recombination between mobile DNA elements (e.g., *Alu* elements) in introns of *two separate* genes also occurred, generating new genes made from novel combinations of preexisting exons (Figure 7-18). This evolutionary process, termed **exon shuffling**, may have occurred during the evolution of the genes encoding tissue plasminogen activator, the Neu receptor, and epidermal growth factor, all of which contain an EGF domain (see Figure 3-11). In this case, exon shuffling presumably resulted in the insertion of an EGF domain–encoding exon into an intron of the ancestral form of each of these genes.

FIGURE 7-18 Exon shuffling via recombination between homologous interspersed repeats. Recombination between interspersed repeats in the introns of separate genes produces transcription units with new combinations of exons. In the example shown here, a double crossover between two sets of *Alu* repeats results in an exchange of exons between two genes.

Both DNA transposons and LINE retrotransposons have been shown to occasionally carry unrelated flanking sequences — including exons — when they transpose to new sites by the mechanisms diagrammed in Figure 7-19. This occasional transposition of flanking DNA sequences probably also contributed to exon shuffling during the evolution of contemporary genes.

FIGURE 7-19 Exon shuffling by transposition. (a) Transposition of an exon flanked by homologous DNA transposons into an intron on a second gene. As we saw in Figure 7-10, step **1**, transposase can recognize and cleave the DNA at the ends of the transposon inverted repeats. In gene 1, if the transposase cleaves at the left end of the transposon on the left and at the right end of the transposon on the right, it can transpose all the intervening DNA, including the exon from gene 1, to a new site in an intron of gene 2. The net result is an insertion of the exon from gene 1 into gene 2. (b) Integration of an exon into another gene via LINE transposition. Some LINEs have weak poly(A) signals. If such a LINE is in the $3'$-most intron of gene 1, during transposition its transcription may continue beyond its own poly(A) signals and extend into the $3'$ exon, transcribing the cleavage and polyadenylation signals of gene 1 itself. This RNA can then be reverse-transcribed and integrated by the LINE ORF2 protein (see Figure 7-17) into an intron on gene 2, introducing a new $3'$ exon (from gene 1) into gene 2.

In addition to causing changes in coding sequences, recombination between mobile elements and transposition of DNA adjacent to mobile elements probably played a significant role in the evolution of regulatory sequences that control gene expression. As noted earlier, eukaryotic genes have transcription-control regions called enhancers that can operate over distances of tens of thousands of base pairs. The transcription of many genes is controlled through the combined effects of several enhancer elements. Insertion of mobile elements near such transcription-control regions probably contributed to the evolution of new combinations of enhancer sequences. These combinations, in turn, control which specific genes are expressed in particular cell types and the amount of the encoded protein produced in modern organisms, as we discuss in the next chapter.

These considerations suggest that the early view of mobile DNA elements as completely selfish molecular parasites misses the mark. Rather, these elements have contributed profoundly to the evolution of multicellular organisms by promoting (1) the generation of gene families via gene duplication, (2) the creation of new genes via shuffling of preexisting exons, and (3) the formation of more complex regulatory regions that provide multifaceted control of gene expression. Today researchers are attempting to harness transposition mechanisms to insert therapeutic genes into patients as a form of gene therapy.

A process analogous to that shown in Figure 7-19a is largely responsible for the rapid spread of antibiotic resistance among pathogenic bacteria, a major problem in modern medicine. Bacterial genes encoding enzymes that inactivate antibiotics (drug resistance genes) have become flanked by insertion sequences, generating drug resistance transposons. The widespread use of antibiotics in medicine and agriculture has led to positive selection on drug resistance transposons. These transposons are often found incorporated into conjugating plasmids. Conjugating plasmids encode proteins that result in their replication and transfer to other bacterial cells — even cells of other related bacterial species — through a complex macromolecular tube called a pilus. These plasmids, called *R factors* (for drug *r*esistance), can carry multiple drug resistance genes introduced by transposition and selected in environments, such as hospitals, where antibiotic-laced cleaning

solutions are used to sterilize surfaces. R factors have led to the rapid spread of resistance to multiple antibiotics among pathogenic bacteria. Coping with the spread of R factors is a major challenge for modern medicine. ■

KEY CONCEPTS OF SECTION 7.3

Transposable (Mobile) DNA Elements

- Transposable DNA elements are moderately repeated sequences interspersed at multiple sites throughout the genomes of multicellular eukaryotes. They are present less frequently in unicellular eukaryotic and prokaryotic genomes.
- DNA transposons move to new sites directly as DNA; retrotransposons are first transcribed into an RNA copy of the element, which is then reverse-transcribed into DNA (see Figure 7-8).
- A common feature of all mobile elements is the presence of short direct repeats flanking the element, generated as the result of staggered cuts in the target-site DNA that are filled in by a DNA polymerase during transposition (see Figure 7-10).
- Enzymes called *transposases* encoded by transposons themselves catalyze insertion of these sequences at new sites in genomic DNA.
- Although DNA transposons, similar in structure to bacterial IS elements, occur in eukaryotes (e.g., the *Drosophila* P element), retrotransposons are generally much more abundant, especially in vertebrates.
- LTR retrotransposons are flanked by long terminal repeats (LTRs) similar to those in retrovirus proviral DNA; like retroviruses, they encode reverse transcriptase and integrase. They move in the genome by being transcribed into RNA, which then undergoes reverse transcription in the cytosol, nuclear import of the resulting DNA with LTRs, and integration into a host-cell chromosome (see Figure 7-14).
- Non-LTR retrotransposons, including long interspersed elements (LINEs) and short interspersed elements (SINEs), lack LTRs and have an AT-rich stretch at one end. They are thought to move by a nonviral retrotransposition mechanism mediated by LINE-encoded proteins involving priming of reverse transcription by chromosomal DNA (see Figure 7-17).
- SINE sequences exhibit extensive homology with 7SL small cellular RNA and are transcribed by RNA polymerase III. *Alu* elements, the most common SINEs in humans,

are sequences of about 300 bp found scattered throughout the human genome at about 1.6 million sites (see Figure 7-4a).

- Some interspersed repeats are derived from cellular RNAs that were reverse-transcribed and inserted into genomic DNA at some time in evolutionary history. Processed pseudogenes derived from mRNAs lack introns, a feature that distinguishes them from pseudogenes, which arose by sequence drift of duplicated genes.
- Mobile DNA elements most likely influenced evolution significantly by serving as sites for homologous recombination during unequal crossing over, leading to gene and exon duplication (see Figure 7-2) and exon shuffling (see Figure 7-18), and by mobilizing adjacent DNA sequences (see Figure 7-19).

7.4 Structural Organization of Eukaryotic Chromatin and Chromosomes

Now that we have examined the various types of DNA sequences found in eukaryotic genomes and how they are organized within the single, extremely long DNA molecules contained in each chromosome, we turn to the question of how DNA molecules of this length are organized within eukaryotic cells. Because the total length of cellular DNA (~2 meters in humans) is roughly 100,000 times the diameter of the nucleus (~20 μm for most human cells), the packing of DNA is crucial to cell architecture. It is also essential to prevent the long DNA molecules from getting knotted or tangled with each other during cell division, when they must be precisely segregated to daughter cells.

Packing chromosomal DNA into the nucleus requires a number of proteins, in particular, histones. In this section, we consider the structural organization of histones and DNA to form chromosomes. We also examine the dynamic nature of these structures as they respond to gene expression signals and the changes that occur throughout the cell cycle.

Chromatin Is Made of Nucleosomes

The key molecular structure that allows chromosomal DNA to undergo this incredible compaction is the **nucleosome** (Figure 7-20), which consists of 145–147 base pairs of DNA wrapped tightly ~1 2/3 turns around a symmetrical, roughly globular protein complex called the **histone octamer**. The histone octamer is made of two copies each of four small (~15 kDa), basic proteins. There are five major types of **histone** proteins in eukaryotes termed *H2A, H2B, H3*, and *H4*, for the four histones that make up the histone octamer (Figure 7-20), and histone *H1*, a *linker histone*. One copy of H1 binds linker DNA at the entry and exit sites of the 1 2/3 DNA wraps of 145–147 base pairs around the histone octamer core of the nucleosome (Figures 7-20 and 7-21). The histones are rich in positively charged basic amino acids, which interact with the negatively charged phosphate groups in DNA. The complex of DNA plus histones and other less abundant proteins is called **chromatin**.

Examination of isolated chromatin by standard electron microscopy using staining with heavy metals revealed a "beads-on-a-string" organization of nucleosomes separated by a variable length of DNA of ~50–150 bp called **linker DNA** (Figure 7-22). Until recently, it has not been possible to trace the path of a chromatin fiber in electron micrographs of nuclei of fixed cells because chromatin fibers could not be distinguished from other nuclear macromolecules of similar electron density after staining with standard EM methods. However, a recently developed technique, called *ChromEMT*, has now made this possible. ChromEMT specifically labels DNA in thin sections of fixed cells with the electron opaque compound OsO_4. The resolution is sufficient to reveal chains of nucleosomes that can be traced through EM thin sections (Figure 7-23). Nearly all nuclear DNA was found to be associated with nucleosomes connected by flexible linker DNA. In regions visualized as **euchromatin** in standard electron micrographs, where most expressed genes are located, the linker DNA is extended between nucleosomes (Figure 7-23a) compared to more condensed regions of chromatin, known as **heterochromatin**, where few genes are transcribed. In heterochromatin, the linker DNA is curved and bent so that the

nucleosomes are much closer together than in euchromatin (Figure 7-23a). The regions in the nucleus between nucleosomes in Figure 7-23a that were not stained are not empty but contain RNA as well as thousands of different nuclear proteins that are not stained by ChromEMT. As discussed below, some of these nuclear proteins are thought to control the density of chromatin fibers and the distance between nucleosomes in different regions of the nucleus.

FIGURE 7-22 "Beads-on-a-string" arrangement of nucleosomes in extracted chromatin. (a) Electron micrograph of chromatin extracted from isolated nuclei in a low ionic-strength buffer. The "beads" are nucleosomes (10 nm in diameter) and the "string" is connecting (linker) DNA. (b) A diagram of the beads-on-a-string configuration.

FIGURE 7-23 Heterogeneity in nucleosome interactions and compaction. (a) Human small airway epithelial cells were fixed with glutaraldehyde, stained with ChromEMT (see text), and an EM tomogram was constructed. Scale bar = 100 nm. Arrow indicates the outer nuclear membrane. Regions of euchromatin and heterochromatin are indicated. (b)–(d) DNA and nucleosomes form disordered chromatin chains that have different nucleosome arrangements, conformations, and densities. Three categories of conformations are shown: stack, helical, and loop. Scale bar = 20 nm. (e), (f) Regions of the nucleus from interphase cells (e), and mitotic cells (f). Scale bar = 40 nm.

[Republished with permission from American Association for the Advancement of Science, from H. D. Ou et al., 2017, "ChromEMT: Visualizing 3D Chromatin Structure and Compaction in Interphase and Mitotic Cells," *Science* **357**(6349):eaag0025; https://doi.org/10.1126/science.aag0025; permission conveyed through Copyright Clearance Center, Inc.]

Chromatin is dispersed throughout much of the nucleus in interphase cells (those that are not undergoing mitosis). Further compaction of chromatin during mitosis (see Figure 6-3) produces

the visible *metaphase chromosomes* whose morphology and staining characteristics were detailed by early cytogeneticists. ChromEMT of cells in mitosis reveals that the chromatin fibers are closely packed, making it difficult to trace the chromatin fiber (Figure 7-23f). Although every eukaryotic chromosome includes millions of individual protein molecules, each chromosome contains just one, extremely long, linear DNA molecule. The longest DNA molecules in human chromosomes, for instance, are 2.8×10^8 bp, or almost 10 cm in length. The structural organization of chromatin allows this vast length of DNA to be compacted into the microscopic constraints of a cell nucleus (see Figure 7-1). Despite this degree of compaction, chromatin is organized in such a way that specific DNA sequences within the chromatin are available for cellular processes such as transcription, replication, repair, and recombination.

Chromatin Structure Is Conserved Among Eukaryotes

The general structure of chromatin is remarkably similar in the cells of all eukaryotes, including fungi, plants, and animals, indicating that the structure of chromatin was optimized early in the evolution of eukaryotic cells. The amino acid sequences for the four core histones that make up the nucleosome core (H2A, H2B, H3, and H4) are highly conserved among distantly related species. For example, the sequences of histone H3 from sea urchin and human tissue

differ by only three amino acids, and H3 from the garden pea and human differ by only two amino acids. Apparently, significant deviations from the histone amino acid sequences were selected against during evolution. The similarity in sequence among histones from all eukaryotes indicates that they fold into very similar three-dimensional conformations. The amino acid sequence of H1, however, varies more from organism to organism than do the sequences of the other major histones.

Minor histone variants encoded by genes that differ from the highly conserved major types also exist, particularly in vertebrates. For example, a special form of H2A, designated H2AX, is incorporated in place of H2A in a small fraction of nucleosomes throughout chromatin. At sites of double-stranded breaks in chromosomal DNA, H2AX becomes phosphorylated and participates in the chromosome repair process, probably by functioning as a binding site for repair proteins. In the nucleosomes within centromeres, H3 is replaced by a variant histone called *CENP-A*, which anchors the proteins that bind spindle microtubules during mitosis. Another histone variant, known as *H3.3*, replaces histone H3 in regions of DNA undergoing transcription. The replacement probably occurs when the histone octamer must be moved out of the way by histone chaperones as RNA polymerase is transcribing DNA. These and other minor histone variants differ only slightly in sequence from the major histones. These slight changes in histone sequence may influence the interactions of nucleosomes with other nuclear proteins, the

stability of the nucleosome, and the tendency of chromatin fibers containing the variant histone to condense.

Chromatin Is a Disordered Chain of Nucleosomes Packed Together at Different Concentration Densities in the Nucleus

As mentioned previously, the ChromEMT technique has made it possible to trace chains of nucleosomes separated by linker DNA in thin sections of fixed cells (Figure 7-23). A model for the organization of nucleosomes in a chromatin fiber derived from ChromEMT images of an interphase human cell is shown in Figure 7-24a. These chains of nucleosomes appear to range in diameter from 5 to 24 nm. The narrower dimension is thought to result from a projection of the fiber that shows primarily linker DNA, and the larger dimension from a projection that includes more than one nucleosome. Nucleosomes often contact each other; sometimes appearing to stack on each other (Figure 7-23b), sometimes packing in a helical conformation (Figure 7-23c), and sometimes forming a chain that loops back on itself (Figure 7-23d). Nucleosomes appear to interact with multiple alternative orientations and interacting surfaces. In darker staining regions of heterochromatin adjacent to the inner nuclear membrane (Figure 7-23a, arrow), the 5–24 nm chromatin fibers loop back on themselves frequently and are closer

together than in euchromatin. Figures 7-24b, c show models of heterochromatin and euchromatin based on the ChromEMT images.

FIGURE 7-24 Chromatin is composed of structurally disordered 5- to 24-nm-diameter chains that are packed together at different densities in euchromatic and heterochromatic regions. (a) Model of the chromatin fiber based on ChromEMT of small airway epithelial cells. Histone octamers are represented as orange discs and DNA as a blue tube. Large rectangle frames a region visualized as 24 nm in diameter. Small rectangle frames a region of 5-nm diameter. (b) and (c) Representation of the density of chromatin fibers in euchromatin and heterochromatin, respectively.

Ou et al., 2017, "ChromEMT: Visualizing 3D Chromatin Structure and Compaction in Interphase and Mitotic Cells," *Science* **357**(6349):eaag0025; https://doi.org/10.1126/science.aag0025; permission conveyed through Copyright Clearance Center, Inc. Parts (b) and (c) republished with permission from American Association for the Advancement of Science, from Daniel R. Larson and Tom Mistel, 2017, "The Genome — Seeing It Clearly Now," *Science* **357**(6349):354–355; https://doi.org/10.1126/science.aao1893; permission conveyed through Copyright Clearance Center, Inc.]

Condensed metaphase chromosomes appear to have a chromatin structure similar to heterochromatin. In addition, in the condensed metaphase chromosome the chromatin fiber loops back on itself frequently compared to euchromatin and there are more interactions between nucleosomes, resulting in a high density of closely packed chromatin chains (Figure 7-23e, f, and Figure 7-24b, c). Scaffolding proteins are thought to constrain and compact the flexible chromatin chains into the mitotic chromosome architecture. One family of these chromatin scaffolding proteins is called *structural maintenance of chromosome (SMC) proteins* (Figure 7-25). Significantly, using the ChromEMT technique, higher order folding of regular helical structures of ~30 nm, once thought to account for chromatin condensation in heterochromatin and during mitosis, was not observed.

FIGURE 7-25 Model of SMC complexes bound to chromatin. (a) Model of an SMC protein complex. (b) Model of SMC complex topologically linking two chromatin fibers. (c) Model for chromosome condensation by SMC complexes. See K. Nasmyth and C. H. Haering, 2005, *Ann. Rev. Biochem.* **74**:595.

Ringlike Structure of SMC Protein Complexes

SMC proteins are critical for maintaining the structure of condensed chromosomes during mitosis. In extracts prepared from the large

nuclei of *Xenopus laevis* (African frog) eggs, chromosomes can be induced to condense as they do in intact cells as they enter prophase of mitosis. This condensation fails to occur when one type of SMC protein called *condensin* is depleted from the extract with specific antibodies. Yeast with mutations in a related SMC protein called *cohesin* fail to properly associate sister chromatids following DNA replication in the S phase. As a result, chromosomes do not properly segregate to daughter cells during mitosis (see Chapter 19). Structurally related SMC proteins are required for proper segregation of chromosomes in bacteria and archaea, indicating that SMCs are an ancient class of proteins vital to chromosome structure and segregation in all domains of life.

In the general structure of SMC proteins, each SMC monomer contains a hinge region where the polypeptide folds back on itself, forming a very long coiled-coil region and bringing the N- and C-termini together so they can interact to form a globular head domain (Figure 7-25a). The hinge domain of one monomer (blue in Figure 7-25) binds to the hinge domain of a second monomer (red), forming a roughly U-shaped dimeric complex. The head domains of the monomers have ATPase activity and are linked by members of another small protein family called *kleisins*. The overall SMC complex is a ring with a diameter large enough to accommodate two chromatin fibers (Figure 7-25b) and is capable of linking two circular DNA molecules in vitro. Rings of SMC proteins are proposed to fold the chromatin fiber into loops, as diagrammed in Figure 7-

25c. This model can explain why cleavage of the DNA at a relatively small number of sites leads to rapid dissolution of condensed metaphase chromosome structure, whereas protease cleavage of proteins has only a minor effect on chromosome structure until most of the protein is digested. When the DNA is cut anywhere in a long region of chromatin containing several chromatin loops, the broken ends can slip through the SMC protein rings, untying the topological knots that constrain the loops of chromatin. In contrast, a protease must cut most of the individual rings of SMC proteins before the topological constraints forming the loops are released completely.

Modifications of Histone Tails Control Chromatin Condensation and Function

Each of the histone proteins making up the nucleosome core contains an intrinsically disordered, flexible N-terminus of 19–39 residues extending from the globular structure of the nucleosome (Figure 7-26a). The H2A and H2B proteins also contain a flexible C-terminus extending from the globular histone octamer core. These termini, called *histone tails,* are represented as dashed lines in Figure 7-26a in order to represent their lengths relative to the rest of the nucleosome.

FIGURE 7-26 Post-translational modifications observed on human histones. (a) Model of a nucleosome viewed from the top with histones shown as ribbon diagrams. This model depicts the lengths of the histone tails (dotted lines), which are not visible in the crystal structure (see Figure 7-20). The H2A N-terminal tails are at the bottom, and the H2A C-terminal tails are at the top. The H2B N-terminal tails are toward the bottom on the right and left, and the H2B C-terminal tails are at the bottom center. The H3 N-terminal tails extend between the gyres of DNA near the entry and exit point of DNA wrapping around the histone octamer core, and the H4 N-terminal tails extend downward and upward from the roughly disc-shaped nucleosome. Histones H3 and H4 have short C-terminal tails that are not modified. (b) Summary of post-translational modifications observed in human histones. Histone-tail sequences are shown in the one-letter amino acid code, numbered beginning with 1 at the N-terminus (see Figure 2-14). The main portion of each histone that is part of the histone octamer core is depicted as an oval. These modifications do not all occur simultaneously on a single histone molecule. Rather, specific combinations of a few of these modifications are observed on any one histone. See K. Luger and T. J. Richmond, 1998, *Curr. Opin. Genet. Devel.* **8**:140.

[Part (a) Data from K. Luger et al., 1997, *Nature* **389**:251, PDB ID 1aoi. Part (b) Data from R. Margueron et al., 2005, *Curr. Opin. Genet. Devel.* **15**:163.]

Histone-tail–amino acid residue side chains are subject to multiple types of reversible, post-translational covalent modifications such as acetylation, methylation, phosphorylation, and ubiquitinylation. Figure 7-26b summarizes the most common types of post-translational modifications observed in human histones. A particular histone protein never has all of these modifications simultaneously, but the histones in a single nucleosome may contain several of these modifications simultaneously. The particular combinations of histone-tail post-transcriptional modifications found in different regions of chromatin constitute a *histone code* that influences chromatin function by creating or removing binding sites for chromatin-associated proteins depending on the specific combinations of the modifications present. Here we describe the most abundant kinds of modifications found in histone tails and the association of these modifications with chromatin condensation and function. We end with a discussion of a special case of chromatin condensation, the inactivation of X chromosomes in female mammals.

Histone Acetylation

Histone-tail lysines in the amino termini undergo reversible acetylation and deacetylation. In the acetylated form, the positive charge of the lysine ε-amino group is neutralized. Histone acetylation correlates with increased sensitivity of chromatin DNA to nuclease digestion — an observation indicating that histone

acetylation is associated with a more open form of chromatin. This correlation can be demonstrated by conducting experiments in which isolated nuclei are digested with DNase I. Next the DNA is separated from chromatin protein, digested with a restriction enzyme, and analyzed by Southern blotting. An intact gene treated with a restriction enzyme yields fragments of characteristic sizes. But when the DNA is exposed first to DNase I, there are two possible results seen in the Southern blot. One, the gene is cleaved by DNase I at random sites within the boundaries of the restriction enzyme cut sites. Consequently, any Southern blot bands normally seen with that gene will be lost. Two, the gene is hidden within the chromatin so that DNase I molecules could not access it and cut it up. In that case, the Southern blot would show the characteristic banding pattern for that gene. This method was first used to compare the structure of chromatin in the region of the chicken β-globin gene in cells in which the gene is not transcribed and cells in which the gene is actively transcribed (Figure 7-27). The β-globin gene is transcriptionally inactive in non-erythroid cells (MSB cells), but is actively transcribed in erythroid progenitor cells (erythroblasts). In non-erythroid cells, the histones around the β-globin gene have relatively low levels of acetylation, and the chromatin that contains the β-globin gene is resistant to DNase I. In contrast, in erythroid progenitor cells, the histones around the β-globin gene are acetylated, and the chromatin that contains the β-globin gene is sensitive to DNase I (Figure 7-27). These results indicate that the chromatin structure of non-transcribed DNA in *hypoacetylated*

chromatin makes the DNA less accessible to DNase I than it is in transcribed, *hyperacetylated* chromatin. The proposed model is that in non-erythroid cells, chromatin containing the β-globin gene is folded into condensed structures with closely spaced nucleosomes that sterically inhibit access to the associated DNA by the nuclease, as for the region of heterochromatin near the nuclear envelope indicated in Figure 7-23a. In contrast, the transcribed gene is associated with a more unfolded form of chromatin, which allows the nuclease better access to the associated DNA, as in the regions designated euchromatin in Figure 7-23a. More generally, it is presumed that the condensed chromatin structure around the β-globin gene in non-erythroid cells sterically inhibits the proteins involved in transcription from accessing the β-globin promoter and other transcription control sequences in the DNA. Thus histone acetylation and deacetylation appear to be one means of regulating transcription (see Chapter 8).

EXPERIMENTAL FIGURE 7-27 Nontranscribed genes are less susceptible to DNase I digestion than active genes. Chick embryo erythroblasts at 14 days actively synthesize globin, whereas undifferentiated chicken lymphoblastic leukemia (MSB) cells do not. (a) Nuclei from each type of cell were isolated and exposed to increasing concentrations of DNase I. The nuclear DNA was then extracted and treated with the restriction enzyme *Bam*HI, which cleaves the DNA around the globin sequence and normally releases a 4.6-kb globin DNA fragment. (b) The DNase I- and *Bam*HI-digested DNA was subjected to Southern blot analysis with a probe of labeled cloned adult globin DNA, which hybridizes to the 4.6-kb *Bam*HI fragment. If the globin gene is susceptible to the initial DNase digestion, it should be cleaved repeatedly and would not be expected to show this fragment. As seen in the Southern blot, the transcriptionally active DNA from the 14-day globin-synthesizing cells was sensitive to DNase I digestion, indicated by the absence of the 4.6-kb band at high nuclease concentrations. In contrast, the inactive DNA from MSB cells was resistant to digestion. These results suggest that the inactive DNA is in a more condensed form of chromatin in which the globin gene is shielded from DNase digestion. See J. Stalder et al., 1980, *Cell* **19**:973.

Genetic studies in yeast indicated that *histone acetyl transferases (HATs)*, the enzymes that acetylate specific lysine residues in histones, are required for activation of transcription of a number of genes. These enzymes are now known to have other substrates that influence gene expression in addition to histones. Consequently, they are more generally known as *nuclear lysine acetyl transferases*, or *KATs*, because *K* represents lysine in the single-letter code for amino acids (see Figure 2-14). Conversely, early genetic studies in yeast indicated that complete repression of many yeast genes requires the action of *histone deacetylases (HDACs)* that remove acetyl groups of

acetylated lysines from histone tails, as discussed further in Chapter 8.

Other Specific Histone-Tail Post-Translational Modifications

Histone tails in chromatin undergo a variety of other covalent modifications at specific amino acids in addition to lysine acetylation (see Figure 7-26b). Lysine ε-amino groups can be methylated, a process that prevents acetylation, thus maintaining their positive charge. Moreover, the nitrogen of lysine ε-amino groups can be methylated once, twice, or three times. Arginine side chains can also be methylated. The oxygen in hydroxyl groups of serine and threonine side chains can be reversibly phosphorylated, introducing two negative charges. Each of these post-translational modifications contributes to the binding of chromatin-associated proteins that participate in the control of chromatin condensation and the ability of DNA and RNA polymerases to replicate or transcribe the associated DNA. The last of the most common post-translational modifications of histone tails is monoubiquitinylation. In this process, a single 76–amino acid ubiquitin molecule can be reversibly added to a lysine in the C-terminal tails of H2A and H2B. Recall that addition of multiple, linked ubiquitin molecules to a protein can mark it for degradation by the proteasome (see Figure 3-32). In this case, however, the addition of a single ubiquitin molecule

does not greatly affect the stability of a histone, although it does influence chromatin compaction.

Heterochromatin does not fully decondense following mitosis, remaining in a compacted state during interphase and usually associating with the nuclear envelope, nucleoli, and additional distinct foci (Figure 7-28a). Heterochromatin includes centromeres and telomeres of chromosomes as well as transcriptionally inactive genes. Heterochromatin usually contains histone H3 modified by methylation of lysine 9. In contrast, euchromatin generally contains histone H3 extensively acetylated on lysines 9, 18, and 27, especially at promoters and enhancers where there is also phosphorylation of H3 serine 10 (Figures 7-26b and 7-28b). Methylation of H3 lysine 4 is observed at transcription start sites of most metazoan genes.

FIGURE 7-28 Histone-tail post-translational modifications in heterochromatin versus euchromatin. (a) In this electron micrograph of a bone marrow stem cell, the dark-staining areas in the nucleus outside the nucleolus are heterochromatin. The light-staining, whitish areas are euchromatin. (b) The modifications of histone N-terminal tails in heterochromatin and euchromatin differ, as illustrated here for histone H3. Note in particular that histone tails are generally much more extensively acetylated in euchromatin than in heterochromatin. Heterochromatin is much more condensed (thus less accessible to proteins) and is much less transcriptionally active than is euchromatin. (c) HP1 contributes to the condensation of heterochromatin by binding to histone H3 N-terminal tails

trimethylated at lysine 9, then associating with other histone-bound HP1 molecules. (d) Heterochromatin condensation can spread along a chromosome because HP1 binds the histone methyltransferase (HMT) that methylates lysine 9 of histone H3. This creates a binding site for HP1 on the neighboring nucleosome. The spreading process continues until a boundary element is encountered. See G. Thiel et al., 2004, *Eur. J. Biochem.* **271**:2855, and A. J. Bannister et al., 2001, *Nature* **410**:120.

Reading the Histone Code

The histone code of modified amino acids is read by proteins that bind to the modified histone tails and promote condensation or decondensation of chromatin. For example, eukaryotes express a number of proteins containing a domain called a *chromodomain* that binds to histone tails when they are methylated at specific lysines. One example of such a protein is *heterochromatin protein 1 (HP1*). The chromodomain of HP1 binds the H3 N-terminal tail only when it is di- or trimethylated at lysine 9 (see Figure 7-28b). HP1 also contains a second domain called a *chromoshadow domain* because it is frequently found in proteins that contain a chromodomain. The chromoshadow domain binds to chromoshadow domains in other proteins. Consequently, chromatin containing H3 di- and trimethylated at lysine 9 ($H3K9Me_{2/3}$) is assembled into a condensed chromatin structure by HP1 (see Figure 7-28c, *bottom*), although the structure of this chromatin is as yet not well understood.

In addition to binding to itself, the chromoshadow domain of HP1 also binds the enzyme that methylates H3 lysine 9, an H3K9 *histone methyl transferase (HMT)* (see Figure 7-28d). As a consequence, nucleosomes adjacent to a region of HP1-containing heterochromatin become methylated at lysine 9 (see Figure 7-28d). This methylation creates a binding site for another HP1 that can bind the H3K9 HMT; so in this way, the heterochromatin structure spreads along the chromosome until a *boundary element* is encountered that blocks further spreading. Boundary elements are regions in chromatin where several nonhistone proteins bind to DNA, possibly blocking histone methylation on the other side of the boundary.

Epigenetic Memory

The model of heterochromatin formation in Figure 7-28d provides an explanation for how heterochromatic regions of a chromosome are reestablished following DNA replication during S phase of the cell cycle. When DNA in heterochromatin is replicated, the histone octamers that are di- or trimethylated at H3 lysine 9 are distributed to both daughter chromosomes along with an equal number of newly assembled histone octamers. The H3K9 HMT associated with the H3K9 di- and trimethylated nucleosomes methylates lysine 9 of the newly assembled, neighboring nucleosomes, regenerating the heterochromatin covering the same DNA sequence in both daughter chromosomes. Consequently, heterochromatin is marked with an

epigenetic code that maintains the repression of associated genes in replicated daughter cells. It is referred to as "epi-" genetic because it is not determined by DNA sequence, but rather by the post-translational modifications on the histone tails of the parental chromatin.

There are other protein domains that associate with histone-tail modifications typical of euchromatin. Several proteins involved in stimulating gene transcription, such as the largest subunit of TFIID, contain protein domains of ~62 amino acids called *bromodomains* (see Chapter 8). A bromodomain binds to acetylated histone tails and therefore is associated with transcriptionally active chromatin. TFIID and other bromodomain-containing proteins also have histone acetylase activity, which helps to maintain the chromatin in a hyperacetylated state that is conducive to transcription.

Thus we see that an epigenetic code associated with histone post-translational modifications helps to maintain the transcriptional activity of genes in euchromatin and the repression of genes in heterochromatin through successive cell divisions. These epigenetic codes for heterochromatin and euchromatin are essential during early embryonic development when they maintain the patterns of gene expression established in different cell types as these differentiated cells undergo multiple rounds of cell division. Abnormal alterations in these epigenetic codes have been found to

contribute to the pathogenic replication and behavior of cancer cells (see Chapter 25).

In summary, multiple types of covalent modifications to histone tails influence chromatin structure by altering nucleosome–nucleosome interactions and interactions with additional proteins that participate in or regulate processes such as transcription and DNA replication. The mechanisms and molecular processes governing chromatin modifications that regulate transcription are discussed in greater detail in the next chapter.

Interphase Chromosome Territories

Individual interphase chromosomes are less condensed than metaphase chromosomes (see Figure 7-23e, f). Nonetheless, interphase chromatin is not spread throughout the entire nucleus. In situ hybridization of interphase nuclei with chromosome-specific fluorescently labeled probes (called *chromosome paint probes*) has shown that the DNA of each interphase chromosome is localized within a region of the nucleus (Figure 7-29a). These localized regions are called *chromosome territories*. Note in Figure 7-29b how little overlap there is between chromosomes in an interphase nucleus. The precise position of each chromosome is not the same in different cells, although large chromosomes tend to lie at the periphery of the nucleus and small chromosomes toward the center. Also, repeats of rRNA transcription units on chromosomes 13, 14,

15, 21, and 22, known as *nucleolar organizers*, associate with nucleoli found near the center of the nucleus.

EXPERIMENTAL FIGURE 7-29 During interphase, human chromosomes remain in non-overlapping territories in the nucleus. (a) Fixed interphase human fibroblasts were hybridized in situ to fluorescently labeled probes specific for sequences along the full length of human chromosomes 7 (cyan) and 8 (purple). DNA is stained blue with DAPI. In the diploid cell, each of the two chromosome 7s and two chromosome 8s is restricted to a territory or domain within the nucleus, rather than stretching throughout the entire nucleus. (b) This image from a fixed interphase fibroblast from a human male was made with a method similar to that used in (a), except that chromosome paint probes specific for each chromosome were hybridized to the cell to reveal the locations of nearly all the chromosomes. Some of the chromosomes are not observed in this confocal slice through the nucleus.

X-Chromosome Inactivation in Mammalian Females

An important example of epigenetic repression of gene expression is the random inactivation and condensation of one X chromosome in female mammalian cells. Each female mammal has two X chromosomes, one contributed by the egg (X_m) and one contributed by the sperm (X_p). Early during embryonic development, random inactivation of either X_m or X_p occurs in each somatic cell. From that point forward during embryonic development and in adults, every daughter cell generated by cell division maintains the same inactive X chromosome as its parent cell. As a result, the adult female is a mosaic of clones, about half expressing the genes from X_m and the rest expressing the genes from X_p. Inactivation of one X chromosome is the mechanism of *dosage compensation* in female mammals, a process that ensures that cells of females express proteins encoded on the X chromosome at the same levels as the cells of males, which have only one X chromosome.

Histones associated with an inactive X chromosome have post-translational modifications characteristic of other regions of heterochromatin: hypoacetylation of lysines, di- and trimethylation of histone H3 lysine 9, and H3 lysine 27, and a lack of methylation at histone H3 lysine 4 (see Figure 7-28b). X-chromosome inactivation is controlled by the X-inactivation center, a complex locus containing two transcription units on the X chromosome that determines which of the two X chromosomes will be inactivated in each cell. The X-inactivation center includes the *XIST* gene, which encodes a remarkable, *long nonprotein-coding RNA* that associates with

multiple regions of the X chromosome from which it was transcribed, maintaining silencing of that chromosome.

Although the mechanism of X-chromosome inactivation is not fully understood, it involves several processes, including the action of *Polycomb* protein complexes, which are discussed further in Chapter 8. One subunit of the Polycomb complex contains a chromodomain that binds to histone H3 tails when they are trimethylated at lysine 27. The Polycomb complex also contains a histone methyl transferase specific for H3 lysine 27. This finding helps to explain how the X-inactivation process spreads along large regions of the X chromosome and how it is maintained through DNA replication, apparently in a manner similar to heterochromatization by the binding of HP1 to histone H3 tails methylated at lysine 9 (see Figure 7-28c, d).

The mechanism of X-chromosome inactivation is another example of an epigenetic process; that is, a process that affects the expression of specific genes and is inherited by daughter cells, but is not the result of a change in DNA sequence. In other words, the activity of genes on the X chromosome in female mammals is controlled by chromatin structure, rather than by the nucleotide sequence of the underlying DNA. And the inactivated X chromosome (either X_m or X_p) is maintained as the inactive chromosome in the progeny of all future cell divisions because the

histones are modified in a specific, repressing manner that is faithfully inherited through each cell division.

Topological Domains Within Chromosome Territories

It is now possible to gain information about the three-dimensional spatial organization of chromatin within nuclei of interphase cells using a group of related methods referred to as *chromosome conformation capture* methods. These methods utilize massively parallel DNA sequencing and the ability to sequence tens of millions of 50–100-bp DNA fragments (see Chapter 6). The general strategy of chromosome conformation capture is illustrated in Figure 7-30, where protein-dependent associations between distant regions of chromatin are represented in (a), and regions of chromatin not specifically associated with another region are shown in (b). Step **1**: Intact cells are treated with chemical cross-linkers such as formaldehyde that diffuse through cell membranes and covalently cross-link protein to protein and protein to DNA. Step **2**: The cross-linked chromatin is isolated and either digested with a restriction enzyme or subjected to intense sonication to mechanically shear the DNA into fragments of 200–600 bp. Step **3**: Short oligonucleotide linkers are then ligated to the ends of the DNA fragments. These linkers contain a cytosine linked to a biotin at the C-5 position (see Figure 2-17). Step **4**:After removal of excess linker, the preparation is diluted considerably and subjected to treatment with DNA ligase.

Because the preparation is diluted, ligations occur preferentially between the ends of fragments held in close proximity by cross-links. Step **5**: After ligation, the protein-DNA cross-linking reaction is reversed, the protein is digested with proteases, and the DNA is isolated and further sonicated. Ligated fragments are separated from other fragments using streptavidin, which binds the biotin in the linkers added in step **3**.

FIGURE 7-30 Chromosome conformation capture. (a, b) Strategy of chromatin conformation capture methods. See text for explanation. Gray and blue tubes represent regions of DNA separated by >10 kb in the genome sequence. Biotin is represented by red

flags. Data from E. Lieberman-Aiden, 2009, *Science* **326**:289. (c) Heat map of chromosome conformation capture data for a region of chromosome 6 in mouse embryonic stem cells. The sequence from 49 to 54 Mb from the left end of chromosome 6 is represented on both axes. A value of 100 (dark red) indicates that a sequence anywhere within the 10-kb region on the *x* axis was found ligated to a sequence from anywhere in the 10-kb region on the *y* axis 100 times. Since the probability that two ends generated by sonication will be ligated together is higher for ends that are close together than for ends that are far apart, the intensity of the red color in any pixel indicates the relative proximity of the sequences in the two 10-kb intervals in the nuclei at the time of cross-linking. Inset shows a model of chromatin folding that is consistent with these results.

[Part (c) Data from J. R. Dixon, 2012, *Nature* **485**:376.]

The purified, ligated fragments are then sequenced (step **6**). Ligation points are marked by the duplicated sequence of the oligonucleotide linker (step **4**). Sequences on each side of the ligation point are mapped to the genome. In cases in which the two ends of a single fragment were linked together (Figure 7-30b), the sequences on either side of the oligonucleotide linker sequence will map within a few hundred bases of each other on the genome, since the ligated fragments were only a few hundred bases long. But in cases in which fragments that are distant in the genomic sequence were ligated together because they were cross-linked to proteins holding them together (Figure 7-30a), the sequences will map far apart. The observation of distant (>10 kb) sequences repeatedly ligated to each other implies that their respective regions of chromatin were associated with each other in vivo.

The data from a chromatin conformation capture assay can be plotted on a two-dimensional heat map (Figure 7-30c). In this plot, the sequence of the same portion of the genome is plotted on both the *x* and *y* axes, with each pixel equivalent to 10 kb. The pixel at coordinates *x, y* is colored red where a sequence at coordinate *x* was ligated to a sequence at coordinate *y*. The intensity of the red color is proportional to the numbers of ligation events observed that linked a sequence in the 10-kb interval *x* with a sequence in the 10-kb interval *y*.

Figure 7-30c shows the plot generated for a roughly 5.5-Mb region of chromosome 6 in mouse embryonic stem cells. It is immediately apparent that the genome is divided into regions called *topological domains*, in which a chromosomal region is far more likely to be ligated to another sequence within the same topological domain than it is to be ligated to a sequence in another topological domain. These topological domains are on the order of 200 kb to 1.5 Mb in length, with a median size of 880 kb. For example, sequences in the interval of chromosome 6 between 50.9 Mb and 51.3 Mb (Figure 7-30c, topological domain A) are much more likely to be ligated to each other than to sequences in the interval from 51.3 Mb to 52.2 Mb (topological domain B) or to sequences from any of the other topological domains. In situ hybridization studies showed that sequences within a topological domain lie much closer to each other in the fixed cell nucleus than to sequences the same distance away in base pairs, but in a neighboring topological domain. These results

have been interpreted to indicate that the chromatin fiber is folded into topological domains, as represented in the inset of Figure 7-30c. The topological domains are separated by shorter regions of chromatin, called *boundary elements*, that do not interact with distant regions of chromatin. Boundary elements such as this were discussed earlier where they were observed to block spreading of histone H3 lysine 9 tri-methylation and HP1-binding along chromatin tri-methylated on lysine 9 (see Figure 7-28d). Topological domains are long enough to contain several average-sized genes. One area of current research is exploring what protein-DNA interactions might be responsible for establishing boundary elements between topological domains. As we will see in Chapter 8, related chromosome conformation capture techniques have provided strong evidence that proteins bound to enhancers interact with proteins bound to promoters many kilobases away.

Metaphase Chromosome Structure

Condensation of chromosomes during prophase (see Figure 18-38) appears to involve the formation of many more loops of chromatin (as diagrammed for heterochromatin (see Figure 7-25c), so that the length of each loop is greatly reduced compared with chromatin loops in interphase cells. As a result, chromosomes condense into structures of much greater width than interphase chromosomes and decrease in length several-fold, generating the rod-shaped condensed chromosomes observed during metaphase (Figure 7-31).

Andrew Syred/Science Source.

FIGURE 7-31 Typical metaphase chromosome. As seen in this scanning electron micrograph, the chromosome has replicated and comprises two chromatids, each containing one of two identical DNA molecules. The centromere, where the chromatids are attached at a constriction, is required for their separation late in mitosis. Special telomere sequences at the ends function in preventing chromosome shortening.

Experiments with frog egg extracts have shown that a protein complex called *condensin*, composed of SMC subunits (see Figure 7-25 and Chapter 19), contributes to chromosome condensation using energy from ATP hydrolysis. Ultimately, the full lengths of the two associated daughter chromosomes generated by DNA replication during the previous S phase of the cell cycle (see Figure 1-22) condense into bar-shaped structures (chromatids) that in most eukaryotes are linked at the central constriction called the *centromere* (Figure 7-31).

Additional Nonhistone Proteins Regulate Transcription and Replication

The total mass of the histones associated with DNA in chromatin is about equal to that of the DNA. Interphase chromatin and metaphase chromosomes also contain many other proteins in addition to histones. For instance, thousands of different **transcription factors** are associated with interphase chromatin. The

structure and function of these proteins, which regulate transcription, are examined in Chapter 8. Other low-abundance nonhistone proteins associated with chromatin regulate DNA replication during the eukaryotic cell cycle (see Chapter 19).

A few other nonhistone DNA-binding proteins are present in much larger amounts than the transcription or replication factors. Some of these proteins exhibit high mobility during electrophoretic separation and thus have been designated *HMG (high-mobility group) proteins*. When genes encoding the most abundant HMG proteins are deleted from yeast cells, normal transcription is disturbed in most genes examined. Some HMG proteins have been found to assist in the cooperative binding of several transcription factors to specific DNA sequences that are close to each other, stabilizing multiprotein complexes that regulate transcription of a neighboring gene, as discussed in Chapter 8.

KEY CONCEPTS OF SECTION 7.4

Structural Organization of Eukaryotic Chromosomes and Chromatin

- Each eukaryotic chromosome contains a single extremely long DNA molecule associated with about an equal mass of proteins called histones, as well as less abundant amounts of thousands of different chromatin-associated proteins, forming a DNA-protein complex called *chromatin*.
- The key structural element of chromatin is the nucleosome formed from two copies each of four core histones (H2A, H2B, H3, and H4) that form a globular protein domain around which 147–149 base pairs of DNA are tightly wrapped (see Figure 7-20).

Nucleosomes are strung together by a variable length (~50–150 base pairs) of *linker DNA* between them (see Figure 7-22).

- Using a recently developed method called *ChromEMT* which stains DNA with the electron opaque compound OsO_4, chromatin in fixed cells is observed in the electron microscope as a disordered 5- to 24-nm-diameter granular chain of nucleosomes and linker DNA that is folded into different concentration densities in different regions of the nucleus (see Figures 7-23 and 7-24).
- The chromatin in transcriptionally active regions of DNA, called euchromatin, exists in a more extended form than the chromatin in regions called *heterochromatin* where nucleosomes are more densely packed. Most genes in heterochromatin are transcriptionally repressed. In heterochromatin the chromatin chain folds back on itself at short intervals (see Figure 7-23e, f and Figure 7-24b, c), and nucleosomes associate with each other through many alternative surfaces (Figure 7-23b–d) to a much greater extent than in interphase chromosomes. This results in a large increase in nucleosome density in heterochromatin compared to euchromatin (see Figure 7-23e, f).
- Flexible, intrinsically disordered N-terminal *tails* of 16–39 amino acids extend from the globular region of the histone octamer core (see Figure 7-26a). Histones H2A and H2B also have shorter, intrinsically disordered regions at their C-termini. Amino acid side chains in these histone tails are reversibly modified by acetylation, methylation, phosphorylation, and monoubiquitinylation (see Figure 7-26b), as well as other, less abundant post-translational modifications. These modifications influence chromatin structure by regulating the binding of histone tails to other, less abundant chromatin-associated proteins that control chromatin compaction, transcription, and DNA replication.
- Proteins involved in transcription, replication, and repair, and enzymes such as DNase I, can more easily access the DNA in euchromatin with hyperacetylated histone tails than in chromatin with hypoacetylated histone tails, as in heterochromatin.
- An abundant protein associated with heterochromatin, heterochromatin protein 1 (HP1) uses a chromodomain to bind to histone H3 trimethylated at lysine 9. The chromoshadow domain of HP1 associates with itself and with the histone methyl transferase that methylates H3 lysine 9. These interactions cause condensation of the chromatin fiber and spreading of the heterochromatic structure along the chromosome until a boundary element is encountered (see Figure 7-28c, d).
- One X chromosome in nearly every cell of mammalian females consists of highly condensed heterochromatin, resulting in repression of nearly all genes on that chromosome. This X chromosome inactivation is the dosage compensation mechanism used in mammals so that genes on the X chromosome are expressed at the same level in both males and females.

- In interphase cells, chromosomes are localized to largely non-overlapping territories in the nucleus (see Figure 7-29b).
- The results of chromosome conformation capture experiments indicate that chromatin is organized into topological domains of about 200 kb to 1.5 Mb separated by boundary elements (see Figure 7-30c). Chromatin within a topological domain is more densely packed than the chromatin between topological domains in *boundary elements.* As a result, the chromatin in a topological domain is much more likely to interact with another region of chromatin in the same topological domain than with a region of chromatin in another topological domain (see Figure 7-30c).
- During mitosis, chromosomes condense greatly, decreasing their lengths and increasing their diameters to generate metaphase chromosomes visible by light microscopy. Recent observations using ChromEMT indicate that chromatin fibers in condensed mitotic chromosomes fold back on themselves at shorter intervals than in euchromatin, and that nucleosomes associate with each other with multiple possible orientations and surfaces much more frequently in mitotic chromosomes compared to interphase chromosomes (see Figure 7-23b–d) resulting in the much higher density of nucleosomes in mitotic chromosomes.

7.5 Morphology and Functional Elements of Eukaryotic Chromosomes

Having examined the detailed structural organization of chromosomes in the previous section, we now view them from a more global perspective. Early microscopic observations on the number and size of chromosomes and their staining patterns led to the discovery of many important general characteristics of chromosome structure. Researchers subsequently identified specific regions of chromosomes that are critical to their replication and segregation into daughter cells during cell division. In this section, we discuss these functional elements of chromosomes and consider how chromosomes evolved through rare rearrangements of ancestral chromosomes.

Chromosome Number, Size, and Shape at Metaphase Are Species-Specific

In interphase cells, as noted previously, chromosome territories can be visualized with fluorescently labeled hybridization probes (see Figure 7-29). Because chromosomes condense during mitosis and meiosis (see Figure 7-23e, f) and become visible in the light microscope (see Figure 7-31), almost all cytogenetic work (i.e.,

studies of chromosome morphology) has been done with condensed metaphase chromosomes obtained from dividing cells — either somatic cells in mitosis or dividing gametes during meiosis. At the time of mitosis and meiosis, cells have already progressed through the S phase of the cell cycle and have replicated their DNA (see Chapter 19). Consequently, the chromosomes that become visible during metaphase are *duplicated* structures. Each metaphase chromosome consists of two sister **chromatids**, which are linked at a constricted region, the centromere (see Figure 7-31).

The number, sizes, and shapes of the metaphase chromosomes constitute the **karyotype**, which is distinctive for each species. While somatic cells from one species generally have the same karyotype, species that appear quite similar can have very different karyotypes. Distinct karyotypes among closely related species indicate that similar genetic potential can be organized on chromosomes in very different ways. For example, two species of small deer — the Indian muntjac and Reeves muntjac — contain about the same total amount of genomic DNA. The Indian muntjac contains the smallest number of chromosomes of any mammal, only three pairs of autosomes; one sex chromosome is physically separate, but the other is joined to the end of one autosome (Figure 7-32a). In the Reeves muntjac, however, this DNA is organized into 22 pairs of homologous **autosomes** and two physically separate sex chromosomes (Figure 7-32b).

During Metaphase, Chromosomes Can Be Distinguished by Banding Patterns and Chromosome Painting

Certain dyes selectively stain some regions of metaphase chromosomes more intensely than other regions, producing characteristic banding patterns that are specific for individual chromosomes. The regularity of chromosome bands provides useful visible landmarks along the length of each chromosome and can help to distinguish chromosomes of similar size and shape.

Today the method of chromosome painting greatly simplifies the identification and differentiation of individual chromosomes within a karyotype, many of which have similar sizes and shapes. This technique, a variation of **fluorescence in situ hybridization (FISH)**, makes use of probes specific for sites scattered along the length of each chromosome. The probes are labeled with several different fluorescent dyes with distinct excitation and emission wavelengths. Probes specific for each chromosome are labeled with a predetermined fraction of each of the dyes. After the probes are hybridized to chromosomes and the excess removed, the sample is observed with a fluorescence microscope in which a detector determines the fraction of each dye present at each fluorescing position in the microscopic field. This information is conveyed to a computer, and a special program assigns a false-color image to each type of chromosome (Figure 7-33a). Computer graphics allows the

two homologs of each chromosome to be placed next to each other and numbered according to their decreasing size. Such an image clearly displays the cell's karyotype (Figure 7-33b).

EXPERIMENTAL FIGURE 7-33 Human chromosomes are readily identified by chromosome painting. (a) Image of human chromosomes from a male cell in mitosis made by fluorescence in situ hybridization (FISH) using chromosome paint probes. (b) Alignment of these painted chromosomes by computer graphics to reveal the normal human male karyotype.

Chromosome painting is a powerful method for detecting an abnormal number of chromosomes, such as chromosome 21 trisomy in patients with Down syndrome, or chromosomal translocations that occur in rare individuals and in cancer cells (Figure 7-34). The use of probes with different ratios of fluorescent dyes that hybridize to distinct positions along each normal human chromosome allows finer structural analysis of the chromosomes that can more readily reveal deletions or duplications of

chromosomal regions. The chapter-opening figure illustrates the use of such *multicolor FISH* in analysis of the karyotype of a normal human female.

EXPERIMENTAL FIGURE 7-34 Chromosomal translocations can be analyzed using chromosome painting. Characteristic chromosomal translocations are associated with certain genetic disorders and specific types of cancers. For example, in nearly all patients with chronic myelogenous leukemia, the leukemic cells contain the Philadelphia chromosome, a shortened chromosome 22 [der (22)], and an abnormally long chromosome 9 [der (9)] ("der" stands for derivative). These forms result from a translocation between normal chromosomes 9 and 22. This translocation can be detected (a) by classical banding analysis or (b) by chromosome painting.

Chromosome Painting and DNA Sequencing Reveal the Evolution of Chromosomes

Analysis of chromosomes from different species has provided considerable insight into how chromosomes evolved. For example,

hybridization of chromosome paint probes for chromosome 16 of the tree shrew (*Tupaia belangeri*) to tree shrew metaphase chromosomes revealed the two copies of chromosome 16, as expected (Figure 7-35a). However, when the same chromosome paint probes were hybridized to human metaphase chromosomes, most of the probes hybridized to the long arm of chromosome 10 (Figure 7-35b). Further, when multiple probes for the long arm of human chromosome 10 with different fluorescent dye labels were hybridized to tree shrew metaphase chromosomes, these probes bound to sequences along tree shrew chromosome 16 in the same order in which they bind to human chromosome 10.

FIGURE 7-35 Evolution of primate chromosomes. (a) Chromosome paint probes (yellow) for chromosome 16 of the tree shrew (*T. belangeri*, distantly related to humans) hybridized to tree shrew metaphase chromosomes (red). (b) The same tree shrew chromosome 16 paint probes (green) hybridized to human metaphase chromosomes (red). (c) Proposed evolution of human chromosomes (*bottom*) from the chromosomes of the common

ancestor of all primates (*top*). The proposed common primate ancestor chromosomes are numbered according to their sizes, with each chromosome represented by a different color. The human chromosomes are also numbered according to their relative sizes and labeled with colors taken from the colors of the proposed common primate ancestor chromosomes from which they were derived. Small numbers to the left of the colored regions of the human chromosomes indicate the number of the ancestral chromosome from which the region was derived.

[Parts (a) and (b) Republished with permission of Springer, from S. Muller et al., 1999, "Defining the Ancestral Karyotype of all Primates by Multidirectional Chromosome Painting Between Tree Shrews, Lemurs and Humans," *Chromosoma* **108**(6):393–400; permission conveyed through Copyright Clearance Center, Inc. Part (c) Data from L. Froenicke, 2005, *Cytogenet. Genome Res.* **108**:122.]

Humans and tree shrews had a common ancestor that lived as recently as 85 million years ago. These results indicate that during the evolutionary process of divergence, a long, continuous DNA sequence on one of the ancestral chromosomes became chromosome 16 in tree shrews but evolved into the long arm of chromosome 10 in humans. The phenomenon of genes occurring in the same order on a chromosome in two different species is referred to as conserved **synteny** (derived from Latin for "on the same ribbon"). The presence of two or more genes in a common chromosomal region in two or more species indicates a conserved syntenic segment.

The relationships between the chromosomes of many primates have also been determined by cross-species application of chromosome paint probes. Using these relationships and higher resolution analyses of syntenic regions by DNA sequencing and other methods,

it has been possible to propose the karyotype of the common ancestor of all primates. This karyotype is based on the minimum number of chromosomal rearrangements necessary to generate the regions of synteny in chromosomes of contemporary primates (Figure 7-35c).

Human chromosomes are thought to have been derived by several different mechanisms from a common primate ancestor with 23 autosomes plus the X and Y sex chromosomes (Figure 7-35c). Some human chromosomes were derived without large-scale rearrangements of chromosome structure in the primate ancestor (e.g., human chromosome 1). Others are thought to have evolved by breakage of an ancestral chromosome into two chromosomes (e.g., human chromosomes 14 and 15 by breakage of ancestral chromosome 5) or, conversely, by fusion of two ancestral chromosomes (e.g., human chromosome 2 by fusion of ancestral chromosomes 9 and 11). Still other human chromosomes appear to have been generated by exchanges of parts of the arms of distinct chromosomes, that is, by reciprocal translocation involving two ancestral chromosomes (e.g., a reciprocal translocation between ancestral chromosomes 14 and 21 generated human chromosomes 12 and 22). Analysis of regions of conserved synteny between the chromosomes of many mammals indicates that chromosomal rearrangements by breakage, fusion, and translocation occurred rarely in mammalian evolution, about once every 5 million years. When such chromosomal rearrangements did occur, they very likely

contributed to the evolution of new species that could not interbreed with the species from which they evolved.

Chromosomal rearrangements similar to those inferred for the primate lineage have been inferred for other groups of related organisms, including invertebrate, plant, and fungal lineages. There is excellent agreement between predictions of evolutionary relationships based on analysis of syntenic regions of chromosomes from organisms with related morphology (e.g., among mammals, or among insects with similar body organization) and evolutionary relationships based on the fossil record and on the extent of divergence of DNA sequences for homologous genes. This is a strong argument for the validity of evolution as the process that generated the diversity of contemporary organisms.

Interphase Polytene Chromosomes Arise by DNA Amplification

The larval salivary glands of *Drosophila* species and other dipteran insects contain enlarged interphase chromosomes that are visible in the light microscope. When fixed and stained with a dye that stains DNA, these **polytene chromosomes** are characterized by a large number of reproducible, well-demarcated bands (Figure 7-36a), which have been assigned standardized numbers. The densely staining bands represent regions where the chromatin is more

condensed, and the light interband areas are regions where the chromatin is less condensed. This highly reproducible banding pattern seen in *Drosophila* salivary gland chromosomes provides an extremely powerful method for locating specific DNA sequences along the chromosomes of this species. Chromosomal translocations and inversions are readily detectable by changes in the banding pattern of polytene chromosomes. Also, DNA sequences can be localized along the length of polytene chromosomes by *in situ* hybridization (see Figure 7-36c). Insect polytene chromosomes offer one of the only experimental systems in all of nature in which high resolution microscopic localization studies on decondensed interphase chromosomes are possible.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 7-36 Banding on *Drosophila* polytene salivary gland chromosomes. (a) In this light micrograph of *Drosophila melanogaster* larval salivary gland chromosomes, four chromosomes can be observed (X, 2, 3, and 4), with a total of approximately 5000 distinguishable bands. The banding pattern of light and dark bands results from reproducible differences in the extent of chromatin condensation (from euchromatin-like to heterochromatin-like condensation (see Figure 7-23a) along the length of each of the ~1000 aligned chromosomes in a polytene chromosome. Dark bands are regions of more highly compacted chromatin; light bands, regions of more extended chromatin. The centromeres of all four chromosomes often appear fused at the chromocenter. The telomeres of chromosomes 2 and 3 are labeled (L = left arm; R = right arm), as is the telomere of the X chromosome. (b) The pattern of amplification of chromosome 4 during five replications. Double-stranded DNA is represented by a single line. Telomere and centromere DNA are not amplified. In salivary gland polytene chromosomes, each parental chromosome undergoes about 10 replications $(2^{10} = 1024 \text{ strands})$. (c) Detection of specific DNA sequences by *in situ* hybridization of fluorescently labeled probes.

The left panel shows chromatin conformation (3C) assay data for a region near the telomere of chromosome 2L, with one topological domain at the center of the plot. The position of a fluorescently labeled DNA probe to a region near the center of the topological domain is indicated by a red diamond, and location of probes from the borders of the topological domain, in or near the neighboring boundary elements, are shown in cyan. The right two panels are micrographs of the left end of chromosome 2 in polytene chromosomes hybridized to the fluorescent probes from the borders of the topological domain (cyan) and the fluorescent probe from the middle of the topological domain (red), and stained with DAPI for DNA (blue). The white arrowhead indicates a small interband between bands 22A1-2 and 22A3 in the standardized *Drosophila* polytene chromosome map where the probe from the center of the topological domain hybridizes. Scale bar = 2 μm. See C. D. Laird et al., 1973, *Cold Spring Harbor Symp. Quant. Biol.* **38**:311.

[Part (c) Republished with permission of Elsevier, from K. P. Eagen et al., 2015, "Stable Chromosome Condensation Revealed by Chromosome Conformation Capture," *Cell* **163**(4):934–46; https://doi.org/10.1016/j.cell.2015.10.026; permission conveyed through Copyright Clearance Center, Inc.]

A generalized amplification of DNA gives rise to the polytene chromosomes found in the salivary glands of *Drosophila*. This process, termed *polytenization*, occurs when the DNA repeatedly replicates everywhere except at the telomeres and centromere, but the daughter chromosomes do not separate. The result is an enlarged chromosome composed of many parallel copies of itself, such as 1024 copies resulting from 10 such replications in *Drosophila melanogaster* salivary glands (see Figure 7-36b). The amplification of chromosomal DNA greatly increases gene copy number, presumably to supply sufficient mRNA for protein synthesis in the massive salivary gland cells. *In situ* hybridization studies (see Figure 7-36c) indicate that the dark bands in polytene chromosomes are due to

the alignment in the 1024 chromosomes of topological domains observed by chromatin conformation assays, and that the light bands correspond to alignment of boundary elements.

Three Functional Elements Are Required for Replication and Stable Inheritance of Chromosomes

Although eukaryotic chromosomes differ in length and number among species, cytogenetic studies have shown that they all behave similarly at the time of cell division. Moreover, any eukaryotic chromosome must contain three functional elements in order to replicate and segregate correctly: (1) **replication origins** at which DNA polymerases and other proteins initiate synthesis of DNA (see Figures 5-12 and 5-13); (2) the **centromere**, the constricted region required for proper segregation of daughter chromosomes (see Figure 7-31); and (3) the two ends, or **telomeres**. The yeast transformation studies depicted in Figure 7-37 demonstrated the functions of these three chromosomal elements and established their importance for chromosome function.

Lodish et al., *Molecular Cell Biology*, 9e, © 2

EXPERIMENTAL FIGURE 7-37 Yeast transformation experiments were used to identify the functional chromosomal elements necessary for normal chromosome replication and segregation. In these experiments, plasmids containing the *LEU* gene from normal yeast cells are constructed and introduced into leu^- cells by transfection. If the plasmid is maintained in the leu^- cells, they are transformed to LEU^+ cells by the *LEU* gene on the

plasmid and can form colonies on medium lacking leucine. (a) Sequences that allow autonomous replication (ARS) of a plasmid were identified because their insertion into a plasmid vector containing a cloned *LEU* gene resulted in a high frequency of transformation to LEU^+. However, even plasmids with an ARS exhibit poor segregation during mitosis and therefore do not appear in each of the daughter cells. (b) When randomly broken pieces of yeast DNA are inserted into plasmids containing ARS and *LEU*, some of the subsequently transfected cells produce large colonies, indicating that a high rate of mitotic segregation among their plasmids is facilitating the continuous growth of daughter cells. The DNA recovered from plasmids in these large colonies contains yeast centromere (CEN) sequences. (c) When leu^- yeast cells are transfected with linearized plasmids containing *LEU*, ARS, and CEN, no colonies grow. Addition of telomere (TEL) sequences to the ends of the linear DNA gives the linearized plasmids the ability to replicate as new chromosomes that behave very much like a normal chromosome in both mitosis and meiosis. See A. W. Murray and J. W. Szostak, 1983, *Nature* **305**:189, and L. Clarke and J. Carbon, 1985, *Ann. Rev. Genet.* **19**:29.

As discussed in Chapter 5, replication of DNA begins from sites that are scattered throughout eukaryotic chromosomes. The yeast genome contains many 100-bp sequences, called *autonomously replicating sequences (ARSs)*, that act as replication origins. The observation that insertion of an ARS into a circular plasmid allowed the plasmid to replicate in yeast cells provided the first functional identification of replication origins in eukaryotic DNA (Figure 7-37a).

Even though circular ARS-containing plasmids can replicate in yeast cells, only about 5–20 percent of progeny cells contain the plasmid, because mitotic segregation of the plasmids is faulty. However, plasmids that also carry a CEN sequence, derived from the

centromeres of yeast chromosomes, segregate equally, or nearly so, to both mother and daughter cells during mitosis (Figure 7-37b).

If circular plasmids containing an ARS and a CEN sequence are cut once with a restriction enzyme, the resulting linear plasmids do not transform yeast cells generating LEU^+ colonies that grow on medium lacking leucine unless they contain special telomeric (TEL) sequences ligated to their ends (Figure 7-37c). The first successful experiments involving transfection of yeast cells with linear plasmids were achieved by using the ends of a DNA molecule that was known to replicate as a linear molecule in the ciliated protozoan *Tetrahymena*. During part of the life cycle of *Tetrahymena*, much of the nuclear DNA is repeatedly copied in short pieces to form a so-called *macronucleus*. One of these repeated fragments was identified as a dimer of ribosomal DNA, the ends of which contained a repeated sequence $(G_4T_2)_n$. When a section of this repeated TEL sequence was ligated to the ends of linear yeast plasmids containing ARS and CEN, replication and good segregation of the linear plasmids occurred. The initial cloning and characterization of telomeres garnered the Nobel Prize in Physiology or Medicine in 2009, which was awarded to Elizabeth Blackburn, Carol Greider, and Jack Szostak.

Centromere Sequences Vary Greatly in Length and Complexity

Once the yeast centromere regions that confer mitotic segregation were cloned, their sequences could be determined and compared. The results revealed three regions (I, II, and III) that are conserved among the centromeres on different yeast chromosomes (Figure 7-38a). Short, fairly well-conserved nucleotide sequences are present in regions I and III. Region II does not have a specific sequence, but is AT-rich with a fairly constant length, probably so that regions I and III will lie on the same side of the specialized centromere-associated histone octamer. As mentioned earlier in the discussion of variant histones, this specialized centromere-associated histone octamer contains the usual histones H2A, H2B, and H4, but a variant form of histone H3. Centromeres from all eukaryotes similarly contain nucleosomes with a specialized, centromere-specific form of histone H3, called CENP-A in humans. In the simple kinetochore of *S. cerevisiae*, a protein complex called CBF3 associates with this specialized nucleosome. The CBF3 complex, in turn, associates with several copies of an elongated multiprotein complex called Ndc80 (Figure 7-38b). The Ndc80 complexes initially make lateral interactions with a spindle microtubule and subsequently interact with a Dam1 complex, which forms a ring around the end of the microtubule (Figure 7-38c). This interaction results in an end-on attachment of the centromere to the spindle microtubule. *S. cerevisiae* has by far the simplest centromere known in nature.

FIGURE 7-38 Kinetochore-microtubule interaction in *S. cerevisiae*. (a) Sequence of the simple centromeres of *S. cerevisiae*. Data from L. Clarke and J. Carbon, 1985, *Ann. Rev. Genet.*

19:29. (b) Ndc80 complexes associate with both the microtubule and the CBF3 complex. (c) Diagram of the centromere-associated CBF3 complex and its associated Ndc80 complexes, which associate with a ring of Dam1 proteins at the end of a spindle microtubule. The Ndc80 complexes initially make lateral interactions with the side of a spindle microtubule (*top*) and then associate with the Dam1 ring, making an end-on attachment (*bottom*) to the microtubule. See T. U. Tanaka, 2010, *EMBO J.* **29**:4070.

In the fission yeast *S. pombe*, centromeres are 40–100 kb in length and are composed of repeated copies of sequences similar to those in *S. cerevisiae* centromeres. Multiple copies of proteins homologous to those that interact with *S. cerevisiae* centromeres bind to these much larger *S. pombe* centromeres, and in turn bind the much longer *S. pombe* chromosomes to several microtubules of the mitotic spindle apparatus. In plants and animals, centromeres are megabases in length and are composed of multiple repeats of simple-sequence DNA (see Table 7-1 and Figure 7-6). In humans, centromeres contain several types of repeated simple-sequence DNAs including 2–4 Mb arrays of a 171-bp simple-sequence DNA called *alphoid* DNA, which is bound by nucleosomes containing the CENP-A histone H3 variant.

In multicellular animals and plants, centromeres are many megabases in length. A complex protein structure called the *kinetochore* assembles at these large centromeres and associates with multiple mitotic spindle fibers during mitosis (see Figure 18-43). Homologs of many of the centromere-associated proteins found in the yeasts occur in humans and other multicellular eukaryotes.

Where homologs are not evident in multicellular organisms based on amino acid sequence comparisons (such as the Dam1 complex), alternative complexes with similar properties to the yeast proteins have been proposed to function at kinetochores. The functions of the centromere and of the kinetochore proteins that bind to it during the segregation of sister chromatids in mitosis and meiosis are described in Chapters 18 and 19.

Addition of Telomeric Sequences by Telomerase Prevents Shortening of Chromosomes

Sequencing of telomeres from multiple organisms, including humans, has shown that most are repetitive oligomers with a high G content located in the strand with its 3′ end at the end of the chromosome. The telomere repeat sequence in humans and other vertebrates is TTAGGG. These simple sequences are repeated at the ends of chromosomes for a total of a few hundred base pairs in yeasts and protozoans and a few thousand base pairs in vertebrates. The 3′ end of the G-rich strand extends 12–16 nucleotides beyond the 5′ end of the complementary C-rich strand. This short single-stranded region is bound by proteins that protect the ends of linear chromosomes from attack by exonucleases.

The need for a specialized region at the ends of eukaryotic chromosomes is apparent when we consider that all known DNA polymerases elongate DNA chains at the 3′ end, and all require an RNA or DNA primer. As the replication fork approaches the end of a linear chromosome, synthesis of the leading strand continues to the end of the DNA template strand, completing one daughter DNA double helix. However, because the lagging-strand template is copied in a discontinuous fashion, it cannot be replicated in its entirety (Figure 7-39). When the final RNA primer is removed, there is no upstream strand onto which DNA polymerase can build to fill the resulting gap. Without some special mechanism, the daughter DNA strand resulting from lagging-strand synthesis would be shortened at each cell division.

FIGURE 7-39 Standard DNA replication leads to loss of DNA at the 5′ end of each strand of a linear DNA molecule. Replication of the right end of a linear DNA is shown; the same process occurs at the left end (as can be shown by inverting the figure). As the replication fork approaches the end of the parental DNA molecule, the leading strand can be synthesized all the way to the end of the template strand without the loss of

deoxyribonucleotides. However, since synthesis of the lagging strand requires RNA primers, the right end of the lagging daughter DNA strand would remain as ribonucleotides, which are removed and therefore cannot serve as the template for a replicative DNA polymerase. Alternative mechanisms must be used to prevent successive shortening of the lagging strand with each round of replication.

The problem of telomere shortening is solved by an enzyme that adds telomeric repeat sequences to the ends of each chromosome. The enzyme is a protein-RNA complex called *telomere terminal transferase*, or *telomerase*. Because the sequence of the telomerase-associated RNA serves as the template for addition of deoxyribonucleotides to the ends of telomeres, the source of the enzyme, and not the source of the telomeric DNA primer, determines the sequence added. This was proved by transforming *Tetrahymena* with a mutated form of the gene encoding the telomerase-associated RNA. The resulting telomerase added a DNA sequence complementary to the mutated RNA sequence to the ends of telomeric primers. Thus telomerase is a specialized form of a reverse transcriptase that carries its own internal RNA template to direct DNA synthesis. These experiments also earned the Nobel Prize in Physiology or Medicine for the structure and function of telomeres in 2009.

Figure 7-40 depicts how telomerase, by reverse transcription of its associated RNA, elongates the 3′ end of the single-stranded DNA at the end of the G-rich strand mentioned above. Cells from knockout mice that cannot produce the telomerase-associated RNA exhibit no

telomerase activity, and their telomeres shorten successively with each cell generation. Such mice can breed and reproduce normally for three generations before the long telomere repeats become substantially eroded. Then, the absence of telomere DNA results in adverse effects, including fusion of chromosome termini and chromosome loss. By the fourth generation, the reproductive potential of these knockout mice declines, and they cannot produce offspring after the sixth generation.

FIGURE 7-40 Mechanism of action of telomerase. The single-stranded 3′ terminus of a telomere is extended by telomerase, counteracting the inability of the DNA replication mechanism to synthesize the extreme terminus of linear DNA. Telomerase elongates this single-stranded end by a reiterative reverse-transcription mechanism. The action of the

telomerase from the protozoan *Tetrahymena*, which adds a T_2G_4 repeat unit, is depicted here; other telomerases add slightly different sequences. The telomerase contains an RNA template (red) that base-pairs to the $3'$ end of the lagging-strand template. The telomerase catalytic site then adds deoxyribonucleotides TTG (blue), using the RNA molecule as a template (step **1**). The strands of the resulting DNA-RNA duplex are then thought to slip (translocate) relative to each other so that the TTG sequence at the $3'$ end of the replicating DNA base-pairs to the complementary RNA sequence in the telomerase RNA (step **2**). The $3'$ end of the replicating DNA is then again extended by telomerase (step **3**). Telomerases can add multiple repeats by repetition of steps **2** and **3**. DNA polymerase α-primase can prime synthesis of new Okazaki fragments on this extended template strand. The net result prevents shortening of the lagging strand at each cycle of DNA replication. See C. W. Greider and E. H. Blackburn, 1989, *Nature* **337**:331.

The human genes expressing the telomerase protein and the telomerase-associated RNA are active in germ cells and stem cells, but are turned off in most cells of adult tissues that replicate only a limited number of times or will never replicate again (such cells are called *postmitotic*). However, these genes are activated in most human cancer cells, where telomerase is required for the multiple cell divisions necessary to form a tumor. This phenomenon has stimulated a search for inhibitors of human telomerase as potential therapeutic agents for treating cancer. ■

While telomerase prevents telomere shortening in most eukaryotes, some organisms use alternative strategies. *Drosophila* species maintain telomere lengths by the regulated insertion of non-LTR retrotransposons into telomeres. This is one of the few instances in which a mobile element has a specific function in its host organism.

KEY CONCEPTS OF SECTION 7.5

Morphology and Functional Elements of Eukaryotic Chromosomes

- During metaphase, eukaryotic chromosomes become sufficiently condensed that they can be visualized individually in the light microscope.
- The chromosomal karyotype is characteristic of each species. Closely related species can have dramatically different karyotypes, indicating that similar genetic information can be organized on chromosomes in different ways.
- Banding analysis and chromosome painting are used to identify the different human metaphase chromosomes and to detect translocations and deletions (see Figures 7-33 and 7-34).
- Analysis of chromosomal rearrangements and regions of conserved synteny between related species allows scientists to make predictions about the evolution of chromosomes (see Figure 7-35c). The evolutionary relationships between organisms indicated by these studies are consistent with proposed evolutionary relationships based on the fossil record and DNA sequence analysis.
- The highly reproducible banding patterns of polytene chromosomes make it possible to visualize chromosomal deletions and rearrangements as changes in the normal pattern of bands.
- Three types of DNA sequences are required for a long linear DNA molecule to function as a chromosome: a replication origin, called ARS in yeast; a centromere (CEN) sequence; and two telomere (TEL) sequences at the ends of the DNA (see Figure 7-37).
- Telomerase, a protein-RNA complex, has a special reverse transcriptase activity that completes replication of telomeres during DNA synthesis (see Figure 7-40). In the absence of telomerase, the daughter DNA strand resulting from lagging-strand synthesis is shortened at each cell division (see Figure 7-39).

Review the Concepts

1. Genes can be transcribed into mRNA, in the case of protein-coding genes, or into RNA, in the case of genes such as those that encode ribosomal or transfer RNAs. Define a gene. For the following characteristics, state whether they apply to (a) simple or (b) complex transcription units.
   i. Found in eukaryotes
   ii. Contain introns
   iii. Capable of making multiple proteins from a given gene
2. Sequencing of the human genome has revealed much about the organization of genes. Describe the differences between solitary genes, gene families, pseudogenes, and tandemly repeated genes.
3. Much of the human genome consists of repetitive DNA. Describe the difference between microsatellite and minisatellite DNA. How is this repetitive DNA useful for identifying individuals by the technique of DNA fingerprinting?
4. Mobile DNA elements that can move or transpose to a new site directly as DNA are called DNA transposons. Describe the mechanism by which a bacterial DNA transposon, called an insertion sequence, can transpose.
5. Retrotransposons are a class of mobile elements that transpose via an RNA intermediate. Contrast the mechanism of transposition between retrotransposons that

contain long terminal repeats (LTRs) and those that lack LTRs.

6. Discuss the role that transposons may have played in the evolution of modern organisms. What is exon shuffling? What role do transposons play in the process of exon shuffling?
7. The DNA in a cell associates with proteins to form chromatin. What is a nucleosome? What role do histones play in nucleosomes? How are nucleosomes arranged in condensed 30-nm fibers?
8. How do chromatin modifications regulate transcription? What modifications are observed in regions of the genome that are being actively transcribed? In regions that are not actively transcribed?
9. What is chromosome painting, and how is this technique useful? How can chromosome paint probes be used to analyze the evolution of mammalian chromosomes?
10. Certain organisms contain cells that possess polytene chromosomes. What are polytene chromosomes, where are they found, and what function do they serve?
11. Replication and segregation of eukaryotic chromosomes require three functional elements: replication origins, a centromere, and telomeres. How would a chromosome be affected if it lacked (a) replication origins or (b) a centromere?
12. Describe the problem that occurs during DNA replication at the ends of chromosomes. How are telomeres related to this problem?

CHAPTER 8

Transcriptional Control of Gene Expression

OUTLINE

8.1 Overview of Eukaryotic Transcription
8.2 RNA Polymerase II Promoters and General Transcription Factors
8.3 Regulatory Sequences for Protein-Coding Genes and the Proteins Through Which They Function
8.4 Molecular Mechanisms of Transcription Repression and Activation
8.5 Regulation of Transcription-Factor Activity
8.6 Epigenetic Regulation of Transcription
8.7 Other Eukaryotic Transcription Systems

In previous chapters, we have seen that the properties and functions of each cell type are determined by the proteins it contains. In this chapter and the next, we consider how the kinds and amounts of the various proteins produced by a particular cell type in a multicellular organism are regulated. This regulation of *gene expression* is the fundamental process that controls the development of multicellular organisms such as ourselves from a single fertilized egg cell into the thousands of cell types of which we are made. When gene expression goes awry, cellular properties are altered, a process that all too often leads to the development of cancer. As discussed further in Chapter 25, genes encoding proteins that restrain cell growth are abnormally repressed in cancer cells, whereas genes encoding proteins that promote cell growth and

replication are inappropriately activated in cancer cells. Abnormalities in gene expression also result in developmental defects such as cleft palate, tetralogy of Fallot (a serious developmental defect of the heart that can be treated surgically), and many others.

The basic steps in gene expression — that is, the entire process whereby the information encoded in a particular gene is decoded into a particular protein — are reviewed in Chapter 5. Synthesis of mRNA requires that an *RNA polymerase* initiate transcription (**initiation**), polymerize ribonucleoside triphosphates complementary to the DNA-coding strand (**elongation**), and then terminate transcription (**termination**). In bacteria, ribosomes and translation initiation factors have immediate access to newly formed RNA transcripts, which function as mRNA without further modification. In eukaryotes, however, the initial RNA transcript is subjected to processing that yields a functional mRNA (see Figure 5-27). The mRNA then is transported from its site of synthesis in the nucleus to the cytoplasm, where it is translated into protein with the aid of ribosomes, tRNAs, and translation factors.

Regulation occurs at several of the steps in gene expression outlined above: transcription initiation, elongation, RNA processing, and mRNA export from the nucleus, as well as through control of mRNA degradation, mRNA translation into protein, and protein degradation. The diversity of options for regulating gene expression

results in *differential* protein expression that varies among cell types, developmental stages, or in response to external conditions. Although examples have been found of regulation at each step in gene expression, in multicellular animals (metazoans), the control of transcription initiation and elongation are the most important mechanisms (Figure 8-1). The molecular mechanisms that regulate transcription initiation and elongation are critical for normal development of a multicellular organism, for proper immune responses that protect us from pathogenic microorganisms, and for neurological processes such as learning and memory. When these regulatory mechanisms controlling transcription function improperly, pathological processes may occur. For example, mutations of the *HOXD13* gene result in *polydactyly*, the embryological development of extra digits of the feet and hands (Figure 8-2a). *HOXD13* encodes a *transcription factor* that regulates transcription of multiple genes involved in development of the extremities. Other mutations affecting the function or expression of transcription factors cause an extra pair of wings to develop in *Drosophila* (Figure 8-2b) or alter the structures of flowers in plants (Figure 8-2c), among many other developmental abnormalities.

FIGURE 8-1 Contributions of the major processes that regulate protein concentrations. The concentration of a protein is controlled by regulation of the frequency with which the mRNA encoding the protein is synthesized (gene transcription), the rate at which that mRNA is degraded, the rate at which that mRNA is translated into protein, and the rate at which that protein is degraded. The relative contributions of these four rates to determining the concentrations of thousands of proteins in cultured mouse fibroblasts were determined by mass spectrometry to measure protein concentrations (see Chapter 3), mRNA sequencing (RNA-seq) to measure mRNA levels (see Chapter 6), protection of mRNA from ribonuclease digestion by associated ribosomes (ribosome footprinting) to estimate translation rates, stable isotope labeling to determine degradation rates, and statistical analysis of the data to correct for inherent biases and errors in these methods.

Transcription is a complex and highly regulated process that results in the expression of specific genes in specific cell types, despite the fact that nearly all cells contain the same chromosomes with the same DNA sequences. In this chapter, we focus on the molecular events in eukaryotic cells that determine when transcription of a gene occurs. Eukaryotic transcription regulation mechanisms make use of the association of DNA with histone octamers, by forming chromatin structures with varying degrees of condensation, and through post-translational modifications of histone tails (Figures 7-26 and 7-28). Figure 8-3 provides an overview of transcription regulation in metazoans and of the processes outlined in this

chapter. We discuss how the RNA polymerases responsible for transcription of different classes of eukaryotic genes bind to promoter sequences to initiate the synthesis of an RNA molecule and how specific DNA sequences function as **transcription-control regions** by serving as the binding sites for transcription factors that regulate transcription. Next we consider how eukaryotic activators and repressors influence transcription through interactions with large multiprotein complexes. Some of these multiprotein complexes modify chromatin condensation, altering the accessibility of chromosomal DNA to transcription factors and RNA polymerases. Other complexes directly influence the frequency at which RNA polymerases bind to promoters and initiate transcription. In metazoans, the RNA polymerase pauses after transcribing a short RNA, and one mechanism for regulating transcription of a gene involves release of the paused polymerase, allowing it to transcribe the rest of the gene. We discuss how transcription of specific genes can be specified by particular combinations of the roughly 1600 transcription factors encoded in the human genome, giving rise to cell-type-specific gene expression. We consider the various ways in which the activities of transcription factors themselves are controlled to ensure that genes are expressed only in the correct cell types and at the appropriate time during their differentiation.

FIGURE 8-3 Overview of eukaryotic transcriptional control. Inactive genes are assembled into regions of condensed chromatin that inhibit RNA polymerases and their initiation factors from binding to promoters. A pioneer transcription factor is able to bind to a specific regulatory sequence in DNA within the condensed chromatin and interact with chromatin co-activators that decondense, acetylate (Ac), and methylate (Me) the chromatin, thus making the DNA more accessible to binding by other activators (green), RNA polymerase II (the polymerase that transcribes protein coding genes), and its general transcription factors (IIA, IIB, … IIH). Additional activator proteins bound to both promoter-proximal sites and to distant enhancers interact with one another and with the multisubunit Mediator complex to assemble RNA polymerase II (Pol II) and general transcription factors on promoters. Alternatively, repressor proteins bind to other transcription-control elements to inhibit transcription initiation by Pol II. They do this by associating with multiprotein co-repressor complexes to condense chromatin. During transcriptional activation, Pol II initiates transcription, but pauses after transcribing fewer than 100 nucleotides due to the action of an elongation inhibitor (NELF) associated with a protein that clamps the polymerase on the DNA template (DSIF). Activators promote the association of the paused complex with an elongation factor (P-TEFb) that releases NELF and allows productive elongation through the gene. See S. Malik and R. G. Roeder, 2010, *Nat. Rev. Genet*. **11**:761.

We also discuss recent studies revealing that RNA-protein complexes in the nucleus can regulate transcription. New methods for sequencing DNA, coupled with reverse transcription of RNA into DNA in vitro, have revealed that much of the genome of eukaryotes is transcribed into low-abundance RNAs that do not encode proteins. Several nuclear *long noncoding RNAs (lncRNAs)* regulate the transcription of protein-coding genes. This finding raises the possibility that transcriptional control by noncoding RNAs may be much more general than is currently understood. Recent advances in mapping the association of transcription factors with specific regions of chromatin across the entire genome in a variety of cell

types have provided the first glimpses of how transcription factors regulate embryonic development from the pluripotent stem cells of the early embryo to the fully differentiated cells that make up most of our tissues. RNA processing and various post-transcriptional mechanisms for controlling eukaryotic gene expression are covered in Chapter 9. Subsequent chapters, particularly Chapters 15, 16, and 21, provide examples of how transcription is regulated by interactions between cells and how the resulting **gene control** contributes to the development and function of the thousands of specific types of cells in multicellular organisms.

8.1 Overview of Eukaryotic Transcription

In bacteria, gene control serves mainly to allow a single cell to adjust to rapid changes in its environment, such as the availability of nutrients, so that its growth and division can be optimized. In contrast, in multicellular organisms the cellular environment is relatively stable. As with bacteria, though, when sudden changes in the environment do occur, eukaryotic cells rapidly induce sets of genes that protect themselves, as we will see in the cellular responses to heat-shock and hypoxia discussed in Chapter 21. However, the most characteristic and biologically far-reaching purpose of gene control in multicellular organisms is execution of the genetic program that underlies embryological development. Generation of the many different cell types that collectively form a multicellular organism depends on the right genes being activated in the right cells at the right time during the developmental period.

In most cases, once a developmental step has been taken by a cell, it is not reversed. In executing their genetic programs, many differentiated cells (e.g., skin cells, red blood cells, and antibody-producing cells) march down a pathway to final cell death, leaving no progeny behind. The fixed patterns of gene control leading to differentiation serve the needs of the whole organism and not the survival of an individual cell.

Bacteria and eukaryotes share two key features of transcriptional control. First, transcription-control regions are associated with genes. Second, specific proteins that bind to a gene's transcription-control regions determine where and how frequently transcription will initiate. Eukaryotic cells exploit chromatin structure to regulate transcription; a mechanism of transcriptional control that is not available to bacteria. In multicellular eukaryotes, many inactive genes are assembled into condensed regions of chromatin, which inhibit binding of the RNA polymerases and general transcription factors required for transcription initiation (see Figure 8-3). **Activator** proteins, which bind to transcription-control regions near the transcription start site of a gene, and also bind to transcription control regions called *enhancers* located kilobases from the transcription start site, promote chromatin decondensation, binding of RNA polymerase to the promoter, and transcriptional elongation. **Repressor** proteins, which bind to alternative control elements, cause condensation of chromatin and inhibition of polymerase binding or elongation. In this section, we discuss general principles of eukaryotic gene control. Subsequent sections of this chapter will address specific aspects of eukaryotic transcription regulation in greater detail.

Regulatory Elements in Eukaryotic DNA Are Found Both Close to and

Many Kilobases Away from Transcription Start Sites

Direct measurements of the transcription rates of multiple genes in different cell types have shown that regulation of transcription, either at the initiation step or during elongation in the promoter proximal region, is the most widespread form of gene control in eukaryotes (as it is in bacteria). In eukaryotes, as in bacteria, a DNA sequence that specifies where RNA polymerase binds and initiates transcription of a gene is called a **promoter**. Transcription from a particular promoter is controlled by DNA-binding proteins that bind to transcription control regions. Individual eukaryotic transcriptional regulatory proteins often can function to either activate or repress transcription, depending on their associations with other proteins. Consequently, they are referred to by the general term **transcription factors**.

The DNA-control elements in eukaryotic genomes to which transcription factors bind are often located much farther from the promoter they regulate than is the case in bacterial genomes. In some cases, transcription factors bind at regulatory sites tens of thousands of base pairs either **upstream** (opposite to the direction of transcription) or **downstream** (in the same direction as transcription) from the promoter. As a result, transcription of a gene may be regulated by the binding of multiple transcription factors to alternative control elements. This directs expression of the same

gene in different types of cells at different times during development.

For example, several transcription-control regions regulate expression of the mammalian gene encoding the transcription factor *Pax6*. As mentioned in Chapter 1, Pax6 protein is required for development of the eye. Pax6 is also required for development of certain regions of the brain and spinal cord and for cells in the pancreas that secrete insulin. Humans with only one functional *Pax6* gene are born with *aniridia*, a lack of irises in the eyes (Figure 1-31d). In mammals, the *Pax6* gene is expressed from at least three alternative promoters that function in different cell types and at different times during embryogenesis (Figure 8-4a).

FIGURE 8-4 Transcription-control regions of the mouse *Pax6* gene and the orthologous human *PAX6* gene. (a) Three alternative *Pax6* promoters are used at distinct times during embryogenesis in different tissues of the developing mouse embryo. Transcription-control regions regulating expression of *Pax6* in different tissues are indicated by colored rectangles. These control regions are some 200–500 bp in length. (b) Expression of a β-galactosidase reporter transgene fused to the 8 kb of mouse DNA upstream from exon 0. A transgenic mouse embryo 10.5 days after fertilization was stained with X-gal to reveal β-galactosidase. Lens pit (LP) is the tissue that will develop into the lens of the eye. Expression was also observed in tissue that will develop into the pancreas (P). (c) Expression in a mouse embryo at 13.5 days after fertilization of a β-galactosidase reporter gene linked to the sequence in part (a) between exons 4 and 5 marked *Retina*. Arrow points to nasal and temporal regions of the developing retina. (d) Human *PAX6* control regions identified in the 600-kb region between the upstream gene RCN1 and the promoter of the downstream ELP4 gene. RCN1 and ELP4 are transcribed to the left. Their exons are shown as black rectangles below the line representing the DNA sequence. *PAX6* exons are diagrammed as red rectangles above the line. The three *PAX6* promoters are shown by rightward arrowheads, and the control

regions shown in (a) are represented by gray rectangles. Regions flanking the gene where the sequence is partially conserved in most vertebrates (as in Figure 8-5a) are shown as ovals. Colored ovals represent sequences that cause expression of a transgene in specific neuroanatomical locations in the zebrafish where transcription control regions can be assayed much more rapidly than in transgenic mice.

Biol.* **205**(1): 79–97; permission conveyed through Copyright Clearance Center, Inc. Part (d) Data from S. Bhatia et al., 2014, *Devel. Biol.* 387:214.]

Researchers often analyze transcription-control regions by preparing recombinant DNA molecules that combine a fragment of DNA to be tested for its ability to regulate transcription with the coding region for a **reporter gene** whose expression is easily assayed. Typical reporter genes include the gene that encodes luciferase, an enzyme that generates light that can be assayed with great sensitivity and over many orders of magnitude of intensity using a luminometer. Other frequently used reporter genes encode green fluorescent protein (GFP) and proteins that fluoresce other colors, which can be visualized by fluorescence microscopy (see Figures 4-9d and 4-16), and *Escherichia coli* β-galactosidase, which generates an intensely blue insoluble precipitate when incubated with the colorless soluble lactose analog X-gal. When transgenic mice are produced containing a β-galactosidase reporter gene fused to 8 kb of DNA upstream from *Pax6* exon 0 (see Figure 8-4a), β-galactosidase is observed in the developing lens, cornea, and pancreas of the embryo halfway through gestation (Figure 8-4b).

Analysis of transgenic mice with smaller fragments of DNA from this region allowed the mapping of the separate transcription-control regions regulating transcription in the pancreas and in both the lens and cornea. Transgenic mice with other reporter gene constructs revealed additional transcription-control regions (see Figure 8-4a). These regions control transcription in the developing retina and in different regions of the developing brain (encephalon). Some of these transcription-control regions are in introns between exons 4 and 5 and between exons 7 and 8. For example, a reporter gene under control of the region labeled *Retina* in Figure 8-4a between exons 4 and 5 led to reporter-gene expression specifically in the retina (Figure 8-4c).

Control regions for many genes are found hundreds of kilobases away from the coding exons of the gene. One method for identifying such distant control regions is to compare the sequences of distantly related organisms. Transcription-control regions for a conserved gene are also often conserved and can be recognized in the background of nonfunctional sequences that diverge during evolution. For example, there is a DNA sequence about 500 kb downstream of the *SALL1* gene that is highly conserved among humans, mice, chickens, frogs, and fish (Figure 8-5a). *SALL1* encodes a transcription factor required for normal development of the limbs. When transgenic mice were produced containing this conserved DNA sequence linked to a β-galactosidase reporter gene (Figure 8-5b), the transgenic embryos expressed a very high level of

β-galactosidase in the developing limb buds (Figure 8-5c). Human patients with deletions in this region of the genome develop with limb abnormalities. These results indicate that this conserved region directs transcription of the *SALL1* gene in the developing limb. Presumably, other transcription-control regions regulate expression of this gene in other types of cells, where it functions in the normal development of the ears, the lower intestine, and kidneys. After discussing the proteins that function with RNA polymerase to carry out transcription in eukaryotic cells, we will return to a discussion of how such distant transcription-control regions, called *enhancers*, function.

EXPERIMENTAL FIGURE 8-5 The human *SALL1* enhancer activates expression of a reporter gene in limb buds of the developing mouse embryo. (a) Graphic representation of the conservation of DNA sequence in a region of the human genome (in the interval of chromosome 16 from 50214 kb to 50220.5 kb) about 500 kb downstream from the *SALL1* gene, which encodes a zinc-finger transcription repressor. A region of roughly 500 bp of nonprotein-coding sequence is conserved

from zebra fish to human. Nine hundred base pairs of human DNA including this conserved region were inserted into a plasmid next to the coding region for *E. coli* β-galactosidase. (b) The plasmid was microinjected into a pronucleus of a fertilized mouse egg and implanted in the uterus of a pseudopregnant mouse to generate a transgenic mouse embryo with the reporter-gene-containing plasmid incorporated into its genome. (c) After 11.5 days of development, at the time when limb buds develop, the fixed and permeabilized embryo was incubated in X-gal, which is converted by β-galactosidase into an insoluble, intensely blue compound. The results showed that the conserved region contains an enhancer that stimulates strong transcription of the β-galactosidase reporter gene specifically in limb buds.

Three Eukaryotic Nuclear RNA Polymerases Catalyze Formation of Different RNAs

The nuclei of all eukaryotic cells examined so far contain three different RNA polymerases, designated I, II, and III. These enzymes elute at different salt concentrations during ion-exchange chromatography, reflecting the differences in their net charges. The three nuclear RNA polymerases also differ in their sensitivity to α-amanitin, a poisonous cyclic octapeptide produced by some mushrooms (Figure 8-6). RNA polymerase I is insensitive to α-amanitin, but RNA polymerase II is very sensitive — the drug binds

near the active site of the enzyme and inhibits translocation of the enzyme along the DNA template. RNA polymerase III has intermediate sensitivity. Each eukaryotic RNA polymerase catalyzes transcription of genes encoding different classes of RNA (Table 8-1). *RNA polymerase I* (Pol I), located in the nucleolus, transcribes genes encoding precursor rRNA (pre-rRNA), which is processed into 28S, 5.8S, and 18S rRNAs. *RNA polymerase III* (Pol III) transcribes genes encoding tRNAs, 5S rRNA, and an array of small stable RNAs, including one involved in RNA splicing (U6) and the RNA component of the signal recognition particle (SRP) involved in directing nascent proteins to the endoplasmic reticulum (see Chapter 13).

EXPERIMENTAL FIGURE 8-6 Liquid chromatography separates and identifies the three eukaryotic RNA polymerases, each with its own sensitivity to α-amanitin. A protein extract from the nuclei of cultured eukaryotic cells was passed through a DEAE Sephadex column and adsorbed protein eluted (black curve) with a solution of constantly increasing NaCl concentration. An aliquot of each fraction of eluate collected from the column was assayed for RNA polymerase activity without (red curve) and with (green shading) 1 μg/ml α-amanitin. This concentration of α-amanitin inhibits polymerase II activity but has no effect on polymerases I and III. Polymerase III is inhibited by 10 μg/ml of α-amanitin (not shown), whereas polymerase I is unaffected even at this higher concentration.

[Data from R. G. Roeder, 1974, *J. Biol. Chem.* **249**:241.]

TABLE 8-1 • Classes of RNA Transcribed by the Three Eukaryotic Nuclear RNA Polymerases and Their Functions

Polymerase	RNA Transcribed	RNA Function
RNA polymerase I	Pre-rRNA (28S, 18S, 5.8S rRNAs)	Ribosome components, protein synthesis
RNA polymerase II	mRNA	Encodes protein
	snRNAs	RNA splicing
	siRNAs	Chromatin-mediated repression, translation control
	miRNAs	Translation control
RNA	tRNAs	Protein synthesis

polymerase III		
	5S rRNA	Ribosome component, protein synthesis
	snRNA U6	RNA splicing
	7S RNA	Signal recognition particle for insertion of polypeptides into the endoplasmic reticulum
	Other small stable RNAs	Various functions, unknown for many

RNA polymerase II (Pol II) transcribes all protein-coding genes: that is, it functions in production of mRNAs. RNA polymerase II also produces four of the five small nuclear RNAs (snRNAs) that take part in RNA splicing and micro-RNAs (miRNAs) involved in translation control, as well as the closely related endogenous small interfering RNAs (siRNAs) and most of the long noncoding RNAs (lncRNAs) (see Chapter 9). We will be focusing on the regulation of Pol II in this chapter, but we will discuss the regulation of Pol I and Pol III at the end of the chapter.

The eukaryotic RNA polymerases are more complex than bacterial RNA polymerase, but all RNA polymerases have a similar overall design (Figure 8-7a, b). Each eukaryotic RNA polymerase contains two large subunits and 10–14 smaller subunits, some of which are common between two or all three of the polymerases. The best characterized eukaryotic RNA polymerases are from the yeast

Saccharomyces cerevisiae. Each of the yeast genes encoding the polymerase subunits has been subjected to gene-knockout mutations (see Chapter 6) and the resulting phenotypes characterized. In addition, the three-dimensional structure of yeast RNA polymerase II has been determined (Figure 8-7b, c). The three nuclear RNA polymerases from all eukaryotes so far examined are very similar to those of yeast. Plants contain two additional nuclear RNA polymerases (RNA polymerases IV and V), which are closely related to their RNA polymerase II but have a unique large subunit and some additional unique subunits. RNA polymerases IV and V function in transcriptional repression of plant transposons directed by nuclear siRNAs in plants. We discuss them toward the end of this chapter.

FIGURE 8-7 Comparison of three-dimensional structures of bacterial and eukaryotic RNA polymerases. These space-filling models are based on x-ray crystallographic analysis. (a) RNA polymerase from the bacterium *T. aquaticus*. The five subunits of the bacterial enzyme are distinguished by color. Only the N-terminal domains of the α subunits are included in

this model. (b) Core RNA polymerase II from *S. cerevisiae*. Ten of the 12 subunits constituting yeast RNA polymerase II are shown in this model. Subunits that are similar in conformation to those in the bacterial enzyme are shown in the same colors. The C-terminal domain of the large subunit RPB1 was not observed in the crystal structure, but it is known to extend from the position marked with a red arrow. (RPB is the abbreviation for "*R*NA *p*olymerase *B*," which is an alternative way of referring to RNA polymerase II.) DNA entering the polymerases as they transcribe to the right is diagrammed in the top row. (c) Space-filling model of yeast RNA polymerase II including subunits 4 and 7. These subunits extend from the core portion of the enzyme shown in (b) near the region of the C-terminal domain of the large subunit.

[Part (a) see N. Korzheva et al., 2000, *Science* **289**:619–625. Part (b) Data from P. Cramer et al., 2001, *Science* **292**:1863. Part (c) Data from K. J. Armache et al., 2003, *Proc. Nat'l. Acad. Sci. USA* **100**:6964, and D. A. Bushnell and R. D. Kornberg, 2003, *Proc. Nat'l. Acad. Sci. USA* **100**:6969.]

The two large subunits of all eukaryotic RNA polymerases are related in sequence and structure and are also similar to the large *E. coli* RNA polymerase subunits, β′ and β (Figure 8-8 and see Figure 8-7a). Each of the eukaryotic RNA polymerases also contains an ω-like and two nonidentical α-like subunits (see Figure 8-8). The extensive similarity in the structures of these core subunits in RNA polymerases from diverse organisms indicates that RNA polymerase arose early in evolution and has been largely conserved. This seems logical for an enzyme catalyzing a process as fundamental as the copying of RNA from DNA. In addition to the core subunits, all yeast RNA polymerases contain four additional small subunits, which are not in the bacterial RNA polymerase (see Figure 8-8). Finally, each eukaryotic nuclear RNA polymerase has several unique enzyme-specific subunits (see Figure 8-8). Three of these additional subunits of Pol I and Pol III are homologous to the three additional Pol II-

specific subunits. The other two Pol I-specific subunits are homologous to the Pol II general transcription factor TFIIF, discussed later, and the four additional subunits of Pol III are homologous to the Pol II general transcription factors TFIIF and TFIIE. The functions of these general transcription-factor-like subunits in Pol I and Pol III are like those of TFIIE and TFIIF. But during enzyme purification, these subunits remain associated with RNA polymerases I and III, whereas the functionally similar RNA polymerase II subunits separate from RNA polymerase II during purification.

FIGURE 8-8 Schematic representation of the subunit structure of the *E. coli* RNA core polymerase and yeast nuclear RNA polymerases. All three yeast polymerases

have five core subunits homologous to the β, β′, two α, and ω subunits of *E. coli* RNA polymerase. The largest subunit (RPB1) of RNA polymerase II also contains an essential C-terminal domain (CTD). RNA polymerases I and III contain the same two nonidentical α-like subunits, whereas RNA polymerase II contains two other nonidentical α-like subunits. All three polymerases share the same ω-like subunit and four other common subunits. In addition, each yeast polymerase contains three to seven unique smaller subunits.

Archaea, like bacteria, have a single type of RNA polymerase involved in gene transcription, but archaeal RNA polymerases, like eukaryotic nuclear RNA polymerases, have on the order of a dozen subunits. Archaea also possess general transcription factors that are related to those of eukaryotes, which is consistent with the closer evolutionary relationship between archaea and eukaryotes than between bacteria and eukaryotes (see Figure 1-1).

Gene-knockout experiments in yeast indicate that most of the subunits of the three nuclear RNA polymerases are essential for cell viability. Disruption of the genes encoding the few polymerase subunits that are not essential for viability (e.g., subunits 4 and 7 of RNA polymerase II) nevertheless results in cells that grow very poorly. Thus all of the subunits are necessary for eukaryotic RNA polymerases to function normally.

The Clamp Domain Enables RNA Polymerase II to Transcribe Long

Stretches of DNA

Subunit RPBI contains the *clamp domain*, so called because it has been observed to clamp down on DNA that enters the enzyme. In crystals of free Pol II (Figure 8-9a) and in a complex that mimics the elongating form of the enzyme (Figure 8-9b), the clamp domain is in different positions. The domain rotates on a hinge that is open when downstream DNA is inserted into the cleft between RPB1 and RPB2 subunits (see Figure 8-7b), and then swings shut when the enzyme is in its elongation mode (Figure 8-9b). It is postulated that when the 8–9-bp RNA-DNA hybrid region near the active site (where RNA is base-paired to the template strand; see Figure 8-9b) is bound between RBP1 and RBP2 and nascent RNA fills the exit channel, the clamp is locked in its closed position, anchoring the polymerase to the downstream double-stranded DNA. Furthermore, a transcription elongation factor called *DSIF*, discussed later, associates with the elongating polymerase, holding the clamp in its closed conformation. As a consequence, the polymerase is extraordinarily processive, which is to say that it continues to transcribe down the template DNA polymerizing ribonucleotides until transcription is terminated. After termination and release of RNA from the exit channel, the clamp can swing open, releasing the enzyme from the template DNA. This mechanism explains how human RNA polymerase II can transcribe the longest human gene, encoding dystrophin, which is some 2 million base pairs in length, without dissociating and terminating transcription. Since transcription

elongation proceeds at 1–2 kb per minute, transcription of the *DMD* gene requires approximately one day!

FIGURE 8-9 The clamp domain of RPBI. The structures of the free (a) and transcribing (b) RNA polymerase II differ mainly in the position of a clamp domain in the RPB1 subunit (orange), which swings over the cleft between the jaws of the polymerase during formation of the transcribing complex, trapping the template DNA strand and transcript. Binding of the clamp domain to the 8–9-bp RNA-DNA hybrid helps couple clamp closure to the presence of RNA, stabilizing the closed, elongating complex. RNA is shown in red, the template DNA strand in dark blue, and the downstream nontemplate DNA strand in cyan in this model of an elongating complex. The clamp closes over the incoming downstream DNA. This model is shown with portions of RBP2 that form one side of the cleft removed so that the nucleic acids can be better visualized. The Mg^{2+} ion that participates in catalysis of phosphodiester bond formation is shown in green. Wall is the domain of RPB2 that forces the template DNA entering the jaws of the polymerase to bend before it exits the polymerase. The bridge α helix, shown in green, extends across the cleft in the polymerase (see Figure 8-7b) and is postulated to bend and straighten as the polymerase translocates one base down the template strand. The nontemplate strand is thought to form a flexible, single-stranded region above the cleft (not shown), extending from three bases downstream of the template base-paired to the $3'$ base of the growing RNA to where the template strand exits the polymerase, where it hybridizes with the nontemplate strand to generate the transcription bubble.

[Data from A. L. Gnatt et al., 2001, *Science* **292**:1876, PDB ID 1i6h.]

The Largest Subunit in RNA Polymerase II Has an Essential Carboxy-Terminal Repeat

RNA polymerase II contains a unique domain at the carboxyl end of its RPB1 subunit. The domain is made of seven amino acids repeated multiple times. This heptapeptide repeat, with a consensus sequence of Tyr-Ser-Pro-Thr-Ser-Pro-Ser, is known as the **carboxy-terminal domain (CTD)** (see Figure 8-8, red squiggle). Yeast RNA polymerase II contains 26 or more of these repeats, vertebrate enzymes have 52 repeats, and an intermediate number of repeats occurs in RNA polymerase II from nearly all other eukaryotes. The CTD is critical for cell viability, and at least 10 copies of the repeat must be present for yeast to survive.

In vitro experiments with model promoters first showed that RNA polymerase II molecules that initiate transcription have a nonphosphorylated CTD. Once the polymerase initiates transcription and begins to move away from the promoter, many of the serine and some tyrosine residues in the CTD are phosphorylated. Analysis of polytene chromosomes from *Drosophila* salivary glands prepared just before molting of the larva, a time of active transcription, indicates that the CTD is also phosphorylated during in vivo transcription. The large chromosomal "puffs" induced at this time in development are regions where the genome is very actively transcribed. Staining with antibodies specific for either the phosphorylated or nonphosphorylated CTD demonstrated that RNA polymerase II associated with the highly transcribed puffed regions contains a phosphorylated CTD (Figure 8-10).

courtesy of J. R. Weeks and A. L. Greenleaf.

EXPERIMENTAL FIGURE 8-10 Antibody staining demonstrates that the carboxy-terminal domain of RNA polymerase II is phosphorylated during in vivo transcription. Salivary-gland polytene chromosomes were prepared from *Drosophila* larvae just before they molted. The preparation was treated with a rabbit antibody specific for phosphorylated CTD and with a goat antibody specific for nonphosphorylated CTD. The preparation was then stained with fluorescein-labeled anti-goat antibody (green) and rhodamine-labeled anti-rabbit antibody (red). Thus polymerase molecules with a nonphosphorylated CTD stained green, and those with a phosphorylated CTD stained red. The molting hormone ecdysone induces very high rates of transcription in the puffed regions labeled 74EF and 75B; note that only phosphorylated CTD is present in these regions. Smaller puffed regions transcribed at high rates are also visible. Nonpuffed sites that stained red (up arrow) or green (horizontal arrow) are also indicated, as is a site staining both red and green, producing a yellow color (down arrow).

Vivo: Correlations with Gene Activity and Transcript Processing," *Genes Dev.* **7**(12A):2329–2344;]

KEY CONCEPTS OF SECTION 8.1

Overview of Eukaryotic Transcription

- The primary purpose of gene control in multicellular organisms is the execution of precise developmental programs so that the proper genes are expressed in the proper cells at the proper times during embryologic development and cellular differentiation.
- Transcriptional control is the primary means of regulating gene expression in eukaryotes, as it is in bacteria.
- In eukaryotic genomes, DNA transcription-control elements may be located many kilobases away from the promoter they regulate. Different control elements can control transcription of the same gene in different cell types.
- Eukaryotes contain three types of nuclear RNA polymerases. All three contain two large and three smaller core subunits with homology to the β', β, α, and ω subunits of *E. coli* RNA polymerase, as well as several additional small subunits (see Figure 8-8).
- RNA polymerase I synthesizes only pre-rRNA. RNA polymerase II synthesizes mRNAs, some of the small nuclear RNAs that participate in mRNA splicing, micro- and small interfering RNAs (miRNAs and siRNAs) that regulate the translation and stability of mRNAs, and long noncoding (lnc) RNAs that regulate transcription. RNA polymerase III synthesizes tRNAs, 5S rRNA, and several other small stable RNAs (see Table 8-1).
- The carboxy-terminal domain (CTD) in the largest subunit of RNA polymerase II becomes phosphorylated during transcription initiation and remains phosphorylated as the enzyme transcribes the DNA template.

8.2 RNA Polymerase II Promoters and General Transcription Factors

The mechanisms that regulate transcription initiation and elongation by RNA polymerase II have been studied extensively because this polymerase is the one that transcribes mRNAs. Transcription initiation and elongation by RNA polymerase II are the initial biochemical processes required for the expression of protein-coding genes. These are the steps in gene expression that are most frequently regulated and thus determine when and in which cells specific proteins are synthesized. As we mentioned in the previous section, the expression of eukaryotic protein-coding genes is regulated by multiple protein-binding DNA sequences, generically referred to as *transcription-control regions*. These sequences include promoters, which determine where transcription of the DNA template begins, and other types of control elements located near transcription start sites. They also include sequences, called *enhancers*, located far from the genes they regulate, which regulate cell type-specific transcription and how frequently specific genes are transcribed. In this section, we take a closer look at the properties of various transcription-control elements found in eukaryotic protein-coding genes and some techniques used to identify them.

RNA Polymerase II Initiates Transcription at DNA Sequences Corresponding to the 5′ Cap of mRNAs

In vitro transcription experiments using purified RNA polymerase II, a protein extract prepared from the nuclei of cultured cells, and DNA templates containing sequences encoding the 5′ ends of mRNAs for a number of abundantly expressed genes revealed that the transcripts produced always contained a cap structure at their 5′ ends identical to that present at the 5′ end of the spliced mRNA normally expressed from the gene in vivo (see Figure 5-26). In these experiments, the 5′ cap was added to the 5′ end of the nascent RNA by enzymes in the nuclear extract, which can add a cap only to an RNA that has a 5′ tri- or diphosphate. Because a 5′ end generated by cleavage of a longer RNA would have a 5′ monophosphate, it would not be capped. Consequently, researchers concluded that the capped nucleotides generated in the in vitro transcription reactions must have been the nucleotides with which transcription was initiated. Sequence analysis revealed that, for any given gene, the sequence at the 5′ end of the RNA transcripts produced in vitro is the same as that at the 5′ end of the mRNAs isolated from cells, confirming that the capped nucleotide of eukaryotic mRNAs coincides with the transcription start site. Today the transcription start site for a newly characterized mRNA is generally determined simply by identifying

the DNA sequence encoding the 5′-capped nucleotide of the encoded mRNA.

The TATA Box, Initiators, and CpG Islands Function as Promoters in Eukaryotic DNA

Several different types of DNA sequences can function as promoters for RNA polymerase II, directing the polymerase where to initiate transcription of an RNA complementary to the template strand of a double-stranded DNA molecule. These sequences include TATA boxes, initiators, and CpG islands.

TATA Boxes

The first genes to be sequenced and studied through in vitro transcription systems were viral genes and cellular protein-coding genes that are very actively transcribed, either at particular times of the cell cycle or in specific differentiated cell types. In all these highly transcribed genes, a conserved sequence called the **TATA box** was found about 26–31 bp upstream of the transcription start site (Figure 8-11). Mutagenesis studies have shown that a single-base change in this nucleotide sequence drastically decreases in vitro transcription of the gene adjacent to it. If the base pairs between the TATA box and the normal transcription start site are deleted,

transcription of the altered, shortened template begins at a new site about 25 bp downstream from the TATA box.

Initiator Sequences, BREs and DPEs

Instead of a TATA box, some eukaryotic genes contain an alternative core promoter element called an **initiator**. Most naturally occurring initiator elements have a cytosine (C) at the −1 position and an adenine (A) residue at the transcription start site (+1). Directed mutagenesis of mammalian genes with an initiator-containing promoter revealed that the nucleotide sequence immediately surrounding the start site determines the strength of such promoters. In contrast to the conserved TATA box sequence, however, only an extremely degenerate initiator consensus sequence has been defined:

$$(5')\ \text{Y-Y-A}^{+1}\text{-N-T/A-Y-Y-Y}\ (3')$$

where A^{+1} is the base at which transcription starts, Y is a pyrimidine (C or T), N is any of the four bases, and T/A is T or A at position +3. As discussed below, transcription initiation by RNA polymerase II requires several *general transcription factors* (GTFs) that bind with the polymerase to template DNA. The largest of these, TFIID, has two subunits, which together bind the initiator sequence in promoters where it occurs.

Other DNA sequences within ~40 base pairs of the transcription start site can also influence the frequency of transcription initiation. Another GTF, TFIIB, binds to the major groove of DNA immediately upstream of the TATA box, and the strongest promoters contain the optimal sequence for this interaction, called the *TFIIB recognition element (BRE)* (Figure 8-11). Another promoter element designated *DPE* for *downstream promoter element* (Figure 8-11), can be bound by other subunits of TFIID (see below).

FIGURE 8-11 Core promoter elements in metazoans. The sequence of each element is shown with the 5′ end at the left and the 3′ end at the right.

CpG Islands

Transcription of genes with promoters containing a TATA box or initiator element begins at a well-defined initiation site. However, the transcription of ~70 percent of protein-coding genes in mammals occurs at a lower rate than at TATA box–containing and

initiator-containing promoters. For these genes, transcription begins at any of several alternative start sites within regions about 100–1000-bp long that have an unusually high frequency of CG sequences compared to the rest of the genome. Many such genes encode proteins that are not required in large amounts (e.g., genes encoding enzymes involved in basic metabolic processes required in all cells, often called "housekeeping genes"). These promoter regions are called **CpG islands** (where "p" represents the phosphate between the C and G nucleotides) because the sequence 5′ CG 3′ occurs relatively rarely in the genome sequences of mammals, for reasons explained shortly. Within CpG island promoters, the sequence 5′ CG 3′ occurs several times within a few tens of base pairs — a very unusual occurrence in mammalian genomes — leading to the image of rare islands of sequences containing multiple CGs in a sea of genomic sequence bereft of them.

The low frequency of the sequence CG in mammalian genomes is thought to have occurred by the following mechanism: In mammals, most Cs followed by a G are methylated at position 5 of the pyrimidine ring (5-methyl C, represented as C^{Me}; see Figure 2-17). This allows DNA repair mechanisms to distinguish the parental strand of newly replicated DNA containing C^{Me} from the newly synthesized daughter strand lacking C^{Me}, which is more likely to include a mutation introduced by an error in copying the parental strand. In mammalian genomes, CG sequences occur at only ~20 percent their expected frequency based on the percentages of GC

and AT base pairs in their genomes. This is thought to be because the slow, spontaneous deamination of 5-methyl C generates thymidine. Over the time scale of mammalian evolution, this is thought to have led to the conversion of most CGs to TG. As a consequence, the frequency of CG in the human genome is only 21 percent of that expected if Cs were randomly followed by a G. However, the Cs in active CpG island promoters are unmethylated. Consequently, when they deaminate spontaneously, they are converted to U, a base that is recognized by DNA-repair enzymes and converted back to C. As a result, the frequency of CG sequences within CpG island promoters (where they are not methylated) is close to that expected if C were followed by any of the other three nucleotides randomly.

CG-rich sequences are bound by histone octamers more weakly than CG-poor sequences because more energy is required to bend them into the small-diameter loops required to wrap around the histone octamer forming a nucleosome (see Figure 7-20). As a consequence, CpG islands coincide with linker regions of DNA between nucleosomes (see Figure 7-22). Much remains to be learned about the molecular mechanisms that control transcription from CpG island promoters, but a current hypothesis is that the general transcription factors discussed in the next section can bind to them because access to the DNA is not inhibited by DNA interactions with the surface of a histone octamer.

Divergent Transcription from CpG Island Promoters

Another remarkable feature of CpG islands is that transcription from these elements is initiated in both directions, even though only transcription of the sense strand yields an mRNA. By a mechanism(s) that remains to be fully elucidated, most RNA polymerase II molecules transcribing in the "wrong" direction — that is, transcribing the nonsense strand — terminate transcription about 1–3 kb from the transcription start site. This phenomenon was discovered by taking advantage of the stability conferred on the elongation complex by the RNA polymerase II clamp domain when an RNA-DNA hybrid is bound near the active site (see Figure 8-9b).

In one key experiment, nuclei were isolated from cultured human fibroblasts and incubated in a buffered solution containing salt and mild detergent, which removes RNA polymerases except for those in the process of elongation because of their stable association with template DNA. Nucleotide triphosphates were then added, with UTP replaced by bromo-UTP, containing uracil with a Br atom at position 5 on the pyrimidine ring (see Figure 2-17). The nuclei were then incubated at 30 °C long enough for about 100 nucleotides to be polymerized by the RNA polymerase II molecules that were in the process of elongation at the time the nuclei were isolated. RNA was isolated, and RNA containing bromo-U was immunoprecipitated with an antibody specific for BrU-labeled RNA. Thirty-three nucleotides at the 5′ ends of tens of millions of these isolated RNA

molecules were then sequenced by massively parallel DNA sequencing (see Chapter 6) of reverse transcripts, and the sequences were mapped on the human genome. The results of this experiment indicated that approximately equal numbers of RNA polymerase molecules transcribed most promoters (mostly CpG island promoters) in the sense direction *and* in the antisense direction, away from the gene. A peak of sense transcripts was observed at about +50 relative to the major transcription start site (TSS), indicating that at most genes in mammals, Pol II pauses in the +50 to +200 region before elongating further. A peak at −250 to −500 relative to the major transcription start site was also observed for Pol II transcribing in the antisense direction.

These observations, which greatly surprised most molecular biologists when they were first reported, are explained by understanding how transcription factors that bind to promoter sequences function, as we discuss in the following section. Briefly here, multiple processes that regulate the accessibility of DNA at promoters allow proteins known as *general transcription factors* to bind to promoters. At strong promoters with a TATA box or an initiator sequence, the direction of Pol II binding is determined by these promoter sequences and transcription occurs primarily in the sense direction. But at weaker promoters, the general transcription factors and Pol II associate with the promoter DNA in both possible directions randomly, resulting in transcription by half of the polymerases in one direction, and transcription by the other half of

polymerases in the opposite direction. Then, RNA processing, discussed in Chapter 9, results in degradation of the RNAs that were transcribed in the wrong direction so that they are not processed into mRNAs. This apparent waste of energy from widespread antisense transcription followed by degradation of the antisense RNA apparently was not selected against during the evolution of mammals. This is probably because the most abundantly expressed genes are transcribed primarily in the sense direction, and because the amount of energy devoted to mRNA synthesis is only a small fraction of the energy required for other processes essential to mammals such as the movement of our muscles and the constant pumping of the ions required for neurological activity (Chapter 23).

The widely used technique of **chromatin immunoprecipitation** outlined in Figure 8-12a provided additional data supporting the occurrence of divergent transcription from most CpG island promoters in mammals. The method allows one to determine the multiple binding sites of a specific protein along nearly the entire length of the 3×10^9 bp human genome, within a resolution of $\sim$300 base pairs. First, starting with living cells, all proteins are rapidly cross-linked to nearby proteins and other macromolecules including DNA. This is usually done by adding formaldehyde to the media. The cross-linked chromatin is isolated and fragmented into lengths of two to three nucleosomes ($\sim$300 base pairs of DNA). The fragmented chromatin is subjected to immunoprecipitation using an antibody specific for the protein of interest. The data from this analysis are

reported as the number of times a specific sequence from a region of the genome was identified per million total bases of the immunoprecipitated DNA sequenced (Figure 8-12b). At divergently transcribed genes, such as the *Hsd17b12* gene encoding an enzyme involved in intermediary metabolism, two peaks of immunoprecipitated DNA were detected, corresponding to Pol II transcribing in the sense and antisense directions and then pausing. However, only Pol II transcribing in the sense direction was detected more than 1 kb from the start site (TSS). The number of counts per million from this region of the genome >1 kb from the TSS was very low because the gene is transcribed at low frequency. However, the number of counts per million at the transcription start site regions for both sense and antisense transcription was much higher, reflecting the fact that Pol II molecules had initiated transcription in both directions at this promoter, but paused before transcribing farther than 1 kb from the start sites in each direction. In contrast, the *Rpl6* gene, encoding a large ribosomal subunit protein that was abundantly transcribed in the proliferating mouse embryonic stem cells used in the study, was transcribed almost exclusively in the sense direction. The peak in counts per million less than 250 bp from the transcription start site again results from a long pause in transcription in the promoter-proximal region before the polymerase is released to transcribe into the gene. The number of sequence counts per million more than 1 kb downstream from the transcription start site in the sense direction was much higher than

for sense-direction transcription of the *Hsd17b12* gene, reflecting the high rate of transcription of the *Rpl6* gene.

EXPERIMENTAL FIGURE 8-12 Chromatin immunoprecipitation technique localizes where a protein of interest associates with the genome. (a) Step **1**: Live cultured cells or tissues are incubated in 1 percent formaldehyde to covalently cross-link proteins to DNA and proteins to proteins. Step **2**: The preparation is then subjected to sonication to solubilize chromatin and shear it into fragments of 200–500 bp of DNA. Step **3**: An antibody to a protein of interest, here RNA polymerase II, is added, and DNA covalently linked to the protein of interest is immunoprecipitated. Step **4**: The covalent cross-linking is then reversed and the DNA is isolated. The isolated DNA can be analyzed by PCR with primers for a sequence of interest. Alternatively, total recovered DNA can be subjected to massively parallel DNA sequencing. See A. Hecht and M. Grunstein, 1999, *Method. Enzymol.* **304**:399. (b) Results from DNA sequencing of chromatin from mouse embryonic stem cells immunoprecipitated with antibody to RNA polymerase II are shown for a gene that is divergently transcribed (*left*) and a gene that is transcribed only in the sense direction (*right*). Data are plotted as the number of times a DNA sequence in a 50-bp interval was observed per million base pairs sequenced. The region encoding the $5'$ end of the gene is shown below, with exons shown as rectangles and introns as lines.

[Part (b) Data from P. B. Rahl et al., 2010, *Cell* **141**:432.]

General Transcription Factors Position RNA Polymerase II at Transcription Start Sites and Assist in Initiation

Initiation of transcription by RNA polymerase II requires several initiation factors. These initiation factors position Pol II molecules at transcription start sites and help to separate the DNA strands so that the template strand can enter the active site of the enzyme. They are called *general transcription factors* because they are required for transcription of most, if not all, genes transcribed by RNA polymerase II. These proteins are designated *TFIIA, TFIIB*, and so on, and most are multisubunit proteins. The largest is TFIID, which consists of a single 38-kDa **TATA box–binding protein (TBP)** and 13 TBP-associated factors (*TAFs*). General transcription factors with similar activities and homologous sequences are found in all eukaryotes. The complex of Pol II and its general transcription factors bound to a promoter and ready to initiate transcription is called a *preinitiation complex (PIC)*. Figure 8-13a summarizes the current model for the stepwise assembly of the Pol II transcription preinitiation complex on a promoter containing a TATA box. The model is based on cryoelectron microscopy structures of intermediates in the assembly (Figure 8-13b–e).

Lodish et al., *Molecular Cell Biology*, 9e. © 2021 W. H. Freeman and Company

FIGURE 8-13 Model for the sequential assembly of an RNA polymerase II preinitiation complex. (a) The indicated general transcription factors and purified RNA polymerase II (Pol II) bind sequentially to promoter DNA with a TATA box to form a preinitiation complex (PIC). ATP hydrolysis then provides the energy for the unwinding of DNA at the transcription start site by a TFIIH helicase subunit that pushes upstream DNA into the polymerase. The DNA is held in position in the PIC by binding of the TATA box by the TBP subunit of TFIID, and the resulting strain on the structure of the duplex DNA assists the N-terminal region of TFIIB and Pol II to melt the DNA at the transcription start site, forming the transcription bubble. As Pol II initiates transcription in the resulting open complex, the polymerase transcribes away from the promoter, its CTD becomes phosphorylated by the TFIIH kinase domain, and the general transcription factors dissociate from the promoter. Data from S. Sainsbury, C. Berrnecky, and P. Cramer, 2015, *Nat. Rev. Mol. Cell Biol.* **16**:129. (b–e) Cryoelectron microscopy structures of (b) TBP (red), TFIIA (orange), and TFIIB (blue) bound to a strong TATA box promoter. The DNA is not visible because it is obscured by TFIIA and TFIIB. (c) The core PIC composed of TBP-TFIIA-TFIIB-TFIIF-Pol2 bound to promoter DNA. (d) TFIIE bound to the core PIC; (e) TFIIH bound to the core PIC-TFIIE complex, generating the complete, closed preinitiation complex. (f) Diagram of how the TFIIH helicase subunit XPB pushes downstream DNA into the polymerase active site. This distorts the DNA structure because the TATA box is held by TBP, TFIIA, and TFIIB at a fixed distance. This assists the N-terminus of TFIIB and the polymerase in melting the DNA at the transcription start site and inserting the coding strand into the channel between RPB1 and RPB2 where it associates with the polymerase active site, resulting in melting of the transcription start site region, generating the “open complex.”

The TBP subunit of TFIID is the first protein to bind to a TATA box promoter. All eukaryotic TBPs analyzed to date have very similar C-terminal domains of 180 residues. This domain of TBP folds into a saddle-shaped structure; the two halves of the molecule exhibit an overall dyad symmetry but are not identical. TBP interacts with the

minor groove in DNA, bending the helix considerably (see Figure 5-5). The DNA-binding surface of TBP is conserved in all eukaryotes, explaining the high conservation of the TATA box promoter element (see Figure 8-11).

Once TBP has bound to the TATA box, TFIIA and TFIIB can bind (see Figure 8-13a). TFIIA is a heterotrimer larger than TBP, and TFIIB is a monomeric protein, slightly smaller than TBP. TFIIA associates with TBP and DNA on the upstream side of the TBP–TATA box complex. The C-terminal domain of TFIIB clamps onto the C-terminal "stirrup" of the saddle-shaped TBP molecule (see Figure 5-5) and contacts the major groove of DNA on either side of the TATA box. Next, a complex of Pol II and TFIIF, a heterodimer, associates with the promoter DNA-TFIIA-TFIIB complex forming a core *p*romoter *i*nitiation *c*omplex or *core PIC* (see Figure 8-13a). The extended N-terminal domain of TFIIB is inserted into the RNA exit channel of RNA polymerase II (see Figure 8-7c) where it interacts with the double-stranded DNA, stabilizing the complex and helping to hold the DNA in the region of the transcription start site (TSS) over the cleft between RPB1 and RPB2 when the clamp is open (see Figures 8-9a and 8-13a, c).

Next TFIIE, a heterodimer of two different subunits binds next to TIIF, completely enclosing the template DNA in a protein channel over the TSS region, and further stabilizing the complex with promoter DNA (see Figure 8-13d). TFIIE also contains a docking site

for TFIIH, another multisubunit factor nearly as large as the polymerase itself, containing 10 different subunits. Binding of TFIIH completes assembly of the transcription preinitiation complex (see Figures 8-13a closed PIC, and 8-13e).

The **helicase** activity of one of the core TFIIH subunits (XPB in humans, Ssl2 in yeast; see Figure 8-13f) uses energy from ATP hydrolysis to help unwind the DNA duplex at the start site, allowing Pol II to form an *open* complex in which the DNA duplex surrounding the start site is melted and the template strand is bound at the polymerase active site (see Figure 8-13a, Open PIC). As the polymerase transcribes away from the promoter region, the N-terminal domain of TFIIB is released from the RNA exit channel as the 5′ end of the nascent RNA enters it. Three TFIIH subunits form a kinase module (TFIIH in Figure 8-13a) that phosphorylates the Pol II CTD multiple times on serine 5 (underlined) of the Tyr-Ser-Pro-Thr-Ser-Pro-Ser repeat that constitutes the CTD. As we will discuss further in Chapter 9, when multiphosphorylated at Ser5, the CTD is a docking site for the enzymes that form the cap structure (see Figure 5-26) on the 5′ end of an RNA transcribed by RNA polymerase II. In the minimal in vitro transcription assay with TBP substituting for the full TFIID complex, TBP remains bound to the TATA box as the polymerase transcribes away from the promoter region, but the other general transcription factors, and probably the TFIID-TAF subunits, dissociate.

Remarkably, the first subunits of TFIIH to be cloned from humans were identified because mutations in them cause defects in the repair of DNA damaged by alkylation, such as a base with a covalently linked mutagen, or a UV-induced thymidine dimer (see Figure 5-17). In normal individuals, when a transcribing RNA polymerase becomes stalled at a region of damaged template DNA, the core TFIIH complex, lacking the three subunits of the kinase domain (see Figure 8-13a) but including the helicase subunit mentioned above plus an additional helicase subunit whose activity is not required for transcription initiation, recognizes the stalled polymerase and then associates with other proteins that function with TFIIH in repairing the damaged DNA region. In patients with mutant forms of these TFIIH subunits, such repair of damaged DNA in transcriptionally active genes is impaired. As a result, affected individuals have extreme skin sensitivity to sunlight (a common cause of DNA damage through the generation of thymidine dimers) and exhibit a high incidence of cancer. Consequently, these subunits of TFIIH serve two functions in the cell, one in the process of transcription initiation (where one of the helicase subunits helps to open the DNA strands at the transcription start site) and a second in the repair of DNA (where the activities of both helicase subunits are required; see Figure 5-18). Depending on the severity of the defect in TFIIH function, these individuals may suffer from diseases such as xeroderma pigmentosum (see Chapter 25) and Cockayne syndrome (see Chapter 5). ■

The TAF subunits of TFIID function in initiating transcription from promoters that lack a TATA box (>70 percent of human promoters, usually transcribed at lower level compared to TATA box promoters). For instance, some TAF subunits contact the initiator, and or DPE promoter elements (see Figure 8-11) in promoters where they occur (Figure 8-14). This probably explains how such sequences can replace a TATA box (see Figure 8-13) to allow TFIID binding to a TATA-minus promoter.

FIGURE 8-14 Cryoelectron microscopy structure of a closed complex of TFIID, TFIIA, TFIIB, and Pol II bound to promoter DNA. TBP is shown in red, TFIIA in

orange, TAF complexes in light blue, pink, and tan, and Pol II in gray. The color scale at the bottom indicates the sensitivity of the DNA in the complex to digestions by DNase I.

[Republished with permission of Nature Publishing Group, from R. Louder et al., 2016, "Structure of Promoter-Bound TFIID and Model of Human Pre-Initiation Complex Assembly." *Nature* **531**:604–609; https://doi.org/10.1038/nature17394; permission conveyed through Copyright Clearance Center, Inc.]

Chromatin immunoprecipitation assays (see Figure 8-12) using antibodies to TBP show that TBP binds in the region between the divergent transcription start sites in CpG island promoters. Consequently, the general transcription factors required for initiation from promoters containing a TATA box are probably also required for initiation from the weaker CpG island promoters. The absence of any of the promoter elements summarized in Figure 8-11 may account for the divergent transcription from multiple start sites observed from CpG island promoters, since cues from the DNA sequence are not present to correctly orient the preinitiation complex. TFIID and the other general transcription factors may instead choose among nearly equivalent, weak binding sites in CpG island promoters, which may contribute to the low frequency of transcription initiation.

Elongation Factors Regulate the Initial Stages of Transcription in the Promoter-Proximal Region

In metazoans, at most promoters, Pol II pauses after transcribing fewer than 100 nucleotides, due to the binding of a protein called *NELF* (*n*egative *el*ongation *f*actor). NELF binds to Pol II along with an elongation factor called *DSIF* (*D*RB *s*ensitivity-*i*nducing *f*actor, so named because an ATP analog called *DRB* inhibits further transcription elongation in its presence) (Figure 8-15a). The surfaces of Pol II bound by DSIF and NELF are covered by TFIIF and TFIIE in the preinitiation complex, but become exposed when polymerase initiates and separates from the general transcription factors. NELF appears to inhibit transcription elongation by blocking the principal channel through which NTPs reach the active site of the enzyme and by inhibiting conformational changes in the RPB1 and RPB2 subunits of Pol II required for translocation of the enzyme down the template.

FIGURE 8-15 Switch from Pol II pausing to active elongation. The structures of the paused transcription elongation complex Pol II–DSIF–NELF and the

activated elongation complex Pol II–DSIF–PAF–SPT6. The view is along downstream DNA and looking into the polymerase cleft. The general elongation factor DSIF (red) is present in the paused and activated elongation complex, but changes its conformation between the two complexes. The negative elongation factor NELF (blue) stabilizes the paused state. In the activated elongation complex, the positive elongation factor SPT6 (gray) binds the phosphorylated linker to the Pol II CTD, and the PAF complex (purple) binds the polymerase funnel and competes with NELF.

[Republished with permission of Nature Publishing Group, from P. Cramer, 2019, "Organization and Regulation of Gene Transcription." *Nature* **573**:45–54; permission conveyed through Copyright Clearance Center, Inc.]

The inhibition of elongation that results from NELF/DSIF binding to Pol II is relieved when DSIF, NELF, and serine 2 of the Pol II CTD (Tyr-Ser-Pro-Thr-Ser-Pro-Ser) are phosphorylated by the heterodimeric protein kinase CDK9–cyclin T, also called *P-TEFb*, which associates with the Pol II-NELF-DSIF complex, leading to phosphorylation of NELF and DSIF. Phosphorylated NELF dissociates from the complex, allowing two additional elongation factors to bind. These factors, *PAF* and *SPT6* (Figure 8-15b), block further binding of NELF, which allows the polymerase to resume elongation. Phosphorylated DSIF binds to the RPB1 clamp (see Figure 8-9) and RPB2 on the other side of the cleft between RPB1 and RPB2, helping to hold the clamp closed, which allows the polymerase to transcribe long distances without terminating and dissociating from the template. These same elongation factors also regulate transcription from CpG island promoters. So we see that factors that regulate elongation in the promoter-proximal region

provide another mechanism for controlling gene transcription in addition to the many factors that regulate transcription initiation.

Transcription of HIV (human immunodeficiency virus), the cause of AIDS, is dependent on the activation of CDK9–cyclin T by a small viral protein called **Tat**. Cells experimentally infected with *tat*$^-$ mutants produce short viral transcripts about 50 nucleotides long. In contrast, cells infected with wild-type HIV synthesize many more long viral transcripts that encompass the entire integrated proviral genome (see Figure 8-16; also Figure 5-43). Thus Tat functions as an *anti-pausing factor*, permitting RNA polymerase II to read through the transcriptional block caused by NELF binding. (Tat is initially made by rare transcripts that fail to be arrested by NELF when the HIV promoter is transcribed at a high rate in activated T-lymphocytes; see Chapter 24.) Tat is a sequence-specific RNA-binding protein. It binds to the RNA copy of a sequence called *TAR*, which forms a stem-loop structure near the 5′ end of the HIV transcript (Figure 8-16). TAR also binds cyclin T, holding the cyclin T-CDK9 complex close to the polymerase, where it efficiently phosphorylates its substrates, resulting in release of NELF and transcription elongation. Chromatin immunoprecipitation assays done after treating cells with specific inhibitors of CDK9 indicate that transcription of some 30 percent of mammalian genes is regulated by controlling the activity of cyclin T-CDK9 (P-TEFb). This regulation is probably due to interactions between P-TEFb and

sequence-specific DNA-binding transcription factors, rather than by an RNA-binding protein, as in the case of HIV Tat. ■

FIGURE 8-16 Model of antitermination complex composed of HIV Tat protein and several cellular proteins. The TAR element in the HIV transcript contains sequences recognized by Tat and the cellular protein cyclin T. Cyclin T activates and helps position the protein kinase CDK9 near its substrate, the CTD of RNA polymerase II. CTD phosphorylation at serine 2 of the Pol II CTD heptad repeat is required for transcription elongation. Cellular proteins DSIF and the NELF complex are also involved in regulating Pol II elongation, as discussed in the text. See T. Wada et al., 1998, *Genes Dev.* **12**:343; Y. Yamaguchi et al., 1999, *Cell* **97**:451; and T. Yamada et al., 2006, *Mol. Cell* **21**:227.

KEY CONCEPTS OF SECTION 8.2

RNA Polymerase II Promoters and General Transcription Factors

- RNA polymerase II initiates transcription of genes at the nucleotide in the DNA template that corresponds to the $5'$ nucleotide that is capped in the encoded mRNA.
- Four principal types of promoter sequences have been identified in eukaryotic DNA. The TATA box is prevalent in highly transcribed genes. Initiator promoters are found in some genes, and many strong promoters contain a downstream promoter element (DPE) near +30 and a BRE near −35 required for the highest rates of transcription (see Fig 8-11). CpG islands, the promoters for about 70 percent of protein-coding genes in vertebrates, are characteristic of genes transcribed at a low rate.
- Transcription by Pol II of genes with a TATA box promoter is initiated by sequential binding of the following in the indicated order: TFIID, which contains the TBP subunit that binds to TATA box DNA; TFIIA and TFIIB; a complex of Pol II and TFIIF; TFIIE; and finally, TFIIH (see Figure 8-13).
- The helicase activity of a TFIIH subunit helps to separate the DNA strands at the transcription start site in most promoters, a process that requires hydrolysis of ATP. As Pol II begins transcribing away from the start site, its CTD is phosphorylated on serine 5 by the TFIIH kinase domain.
- In metazoans, NELF and DSIF associate with Pol II after initiation, inhibiting elongation to fewer than 100 bp from the transcription start site. Inhibition of elongation is relieved when cyclin T-CDK9 (also called *P-TEFb*) associates with the paused elongation complex and CDK9 phosphorylates subunits of NELF, DSIF, and serine 2 of the Pol II CTD, causing dissociation of NELF from the elongating complex.
- Elongation factors PAF and SPT6 bind to the Pol II surfaces bound by NELF, preventing further NELF binding, and preventing opening of the cleft between RPB1 and RBP2, assisting in long distance processive elongation.

8.3 Regulatory Sequences for Protein-Coding Genes and the Proteins Through Which They Function

As we have seen, expression of eukaryotic protein-coding genes is regulated by multiple DNA sequences, generically referred to as *transcription-control regions*. These regions include promoters and other types of control elements located near transcription start sites, as well as sequences located far from the genes they regulate. In this section, we take a closer look at the properties of various control elements found in eukaryotic protein-coding genes and the proteins that bind to them.

Promoter-Proximal Elements Help Regulate Eukaryotic Genes

Recombinant DNA techniques have been used to systematically mutate the nucleotide sequences of various eukaryotic genes in order to identify transcription-control regions. The use of *linker scanning mutagenesis*, for example, can pinpoint the sequences within a regulatory region that function to control transcription. In this approach, a set of constructs with contiguous overlapping mutations are assayed for their effect on expression of a reporter

gene or production of a specific mRNA (Figure 8-17a). This type of analysis identified **promoter-proximal elements** of the thymidine kinase (*tk*) gene from herpes simplex type I virus (HSV-I). The results demonstrated that the DNA region upstream of the HSV-I *tk* gene contains three separate transcription-control sequences: a TATA box in the interval from −32 to −16 and two other control elements farther upstream (Figure 8-17b). Experiments using mutants containing single-base-pair changes in promoter-proximal control elements revealed that these elements are generally about 6–12 bp long. In human genes, promoter-proximal elements are usually defined as being within ∼200 bp of a transcription start site (TSS). In vertebrates, promoter-proximal elements are found both upstream and downstream of the TSS at equal frequency. While, strictly speaking, the term *promoter* refers to the DNA sequence that determines where a polymerase initiates transcription, the term is often used to refer to both a promoter and its associated promoter-proximal control elements.

EXPERIMENTAL FIGURE 8-17 Linker scanning mutations identify transcription-control elements. (a) In linker scanning mutagenesis, a region of eukaryotic DNA (tan) that supports high-level expression of a reporter gene (light purple) is cloned in a plasmid vector as diagrammed at the top. Overlapping linker scanning (LS) mutations (crosshatched areas) are introduced from one end of the region being analyzed to the other. These mutations are created by scrambling the nucleotide sequence in a short stretch of the DNA. After the mutant plasmids are transfected separately into cultured cells, the activity of the reporter-gene product is assayed. In the example shown here, the sequence from −120 to +1 of the herpes simplex virus thymidine kinase gene, LS mutations 1, 4, 6, 7, and 9 have little or no effect on expression of the reporter gene, indicating that the regions altered in these mutants contain no control elements. Reporter-gene expression is significantly reduced in mutants 2, 3, 5, and 8, indicating that control elements (brown) lie in the

intervals shown at the bottom. (b) Analysis of these LS mutations identified a TATA box and two promoter-proximal elements (PE-1 and PE-2). See S. L. McKnight and R. Kingsbury, 1982, *Science* **217**:316.

In bacteria, regulation of transcription by a control element close to a promoter generally requires its precise localization relative to the transcription start site (TSS). For example, stimulation of *E. coli lac* operon transcription by CAP protein (cyclic AMP-regulated activator protein) is completely lost when two base pairs are inserted between the CAP protein binding site and the TSS. Extensive experimental analyses in *E. coli* have shown that this is because transcriptional activation by CAP requires highly specific direct interactions between CAP bound to its specific binding site in DNA and *E. coli* RNA polymerase bound to the *lac* promoter. Insertion of two base pairs between their binding sites rotates the CAP site 72° relative to the polymerase and moves it ~70 Å away, preventing the interactions between CAP and RNA polymerase required to stimulate transcription.

To test the spacing constraints on control elements in the HSV-I *tk* promoter region identified by analysis of linker scanning mutations, researchers prepared and assayed constructs containing small deletions and insertions between the elements. Changes in spacing between the promoter and promoter-proximal control elements of 20 bp or fewer had little effect. However, insertions of 30–50 bp between a HSV-I *tk* promoter-proximal element and the TATA box

was equivalent to deleting the element. Similar analyses of other eukaryotic promoters have also indicated that considerable flexibility in the spacing between promoter-proximal elements is generally tolerated, but that separations of several tens of base pairs may decrease transcription.

Distant Enhancers Often Stimulate Transcription by RNA Polymerase II

Transcription from many eukaryotic promoters can also be stimulated by control elements located thousands of base pairs away from the transcription start site. Such long-distance transcription-control elements, referred to as **enhancers**, are common in eukaryotic genomes but fairly rare in bacterial genomes. Procedures such as linker scanning mutagenesis have indicated that enhancers, usually on the order of 200 bp long, are, like promoter-proximal elements, composed of several functional sequence elements of about 6–12 bp each. As we will see, each of these regulatory elements is a binding site for a sequence-specific DNA-binding transcription factor.

Analyses of many different metazoan enhancers have shown that they can occur with equal probability upstream from a promoter or downstream from a promoter, where they are within an intron, or even downstream from the final exon of a gene, as in the case of the

SALL1 gene (see Figure 8-5a). Many enhancers are cell-type-specific. For example, an enhancer controlling *Pax6* expression in the retina is found in the intron between exons 4 and 5 (see Figure 8-4a), whereas an enhancer controlling *Pax6* expression in the hormone-secreting cells of the pancreas is located in a roughly 200-bp region upstream of exon 0 (so named because it was discovered after the exon called "exon 1").

Most Eukaryotic Genes Are Regulated by Multiple Transcription-Control Elements

Initially, enhancers and promoter-proximal elements were thought to be distinct types of transcription-control elements. However, as more enhancers and promoter-proximal elements were analyzed, the distinctions between them became less clear. For example, both types of elements can generally stimulate transcription even when inverted, and both types are often cell-type-specific. The consensus now is that a spectrum of control elements regulates transcription by RNA polymerase II. At one extreme are enhancers, which can stimulate transcription from a promoter tens of thousands of base pairs away. At the other extreme are promoter-proximal elements, such as the upstream elements controlling the HSV-I *tk* gene, which lose their influence when moved 30–50 bp farther from the promoter. Researchers have identified a large number of

transcription-control elements that can stimulate transcription from distances between these two extremes.

Figure 8-18a summarizes the locations of transcription-control sequences for a hypothetical mammalian gene with a promoter containing a TATA box. The transcription start site encodes the first (5′) nucleotide of the first exon of an mRNA, the nucleotide that is capped. In addition to the TATA box at about −31 to −26, promoter-proximal elements, which are relatively short (∼6–10 bp), are located within the first 200 bp either upstream or downstream of the start site. Enhancers, in contrast, are usually about 50–200 bp long and are composed of multiple elements of about 6–10 bp. Enhancers may be located up to 50 kb or more upstream or downstream from the start site or within an intron. Like the *Pax6* gene, many mammalian genes are controlled by multiple enhancer regions that function in different types of cells.

FIGURE 8-18 General organization of control elements that regulate gene expression in multicellular eukaryotes and yeast. (a) Mammalian genes with a TATA box promoter are

regulated by promoter-proximal elements and enhancers. The promoter elements shown in Figure 8-11 position RNA polymerase II to initiate transcription at the start site and influence the rate of transcription. Enhancers may be either upstream or downstream and as far away as hundreds of kilobases from the transcription start site. In some cases, enhancers lie within introns. Promoter-proximal elements are found upstream and downstream of transcription start sites at equal frequency in mammalian genes. (b) For mammalian genes with a CpG island promoter, transcription initiates at several sites in both the sense and antisense directions from the ends of the CpG-rich region. Transcripts in the sense direction are elongated and are processed into mRNAs by RNA splicing. These genes express mRNAs with alternative 5′ exons determined by the transcription start site. Genes with CpG island promoters contain promoter-proximal control elements. Currently, it is not clear whether they are also regulated by distant enhancers. (c) Most *S. cerevisiae* genes contain only one regulatory region, called an *upstream activating sequence (UAS)*, and a TATA box, which is about 90 bp upstream from the transcription start site.

Figure 8-18b summarizes the promoter region of a mammalian gene with a CpG island promoter. About 70 percent of mammalian genes are expressed from CpG island promoters, usually at much lower levels than genes with TATA box promoters. Multiple alternative transcription start sites are used, generating mRNAs with alternative 5′ ends for the first exon derived from each start site. Transcription occurs in both directions, but Pol II molecules transcribing in the sense direction are elongated to 3 kb or more much more efficiently than transcripts in the antisense direction.

In the model organism *S. cerevisiae* (budding yeast), genes are closely spaced (see Figure 7-4c), and few genes contain introns. In this organism, enhancers, which are referred to as **upstream activating sequences (UASs)**, usually lie within 200 bp upstream of the

promoters of the genes they regulate. Most yeast genes contain only one UAS. In addition, *S. cerevisiae* genes contain a TATA box about 90 bp upstream from the transcription start site (Figure 8-18c).

DNase I Footprinting and EMSA Detect Protein-DNA Interactions

The various transcription-control elements found in eukaryotic DNA are binding sites for regulatory proteins called *transcription factors*. The simplest eukaryotic cells encode hundreds of transcription factors, and the human genome encodes at least 1600. The transcription of each gene in the genome is independently regulated by *combinations of specific transcription factors* that bind to the gene's transcription-control regions. The number of possible combinations of this many transcription factors is astronomical, sufficient to generate unique controls for every gene encoded in the genome.

In yeast, *Drosophila*, and other genetically tractable eukaryotes, numerous genes encoding transcription activators and repressors have been identified by classical genetic analyses like those described in Chapter 6. However, in mammals and other vertebrates, which are less amenable to such genetic analysis, most transcription factors have been detected initially and subsequently purified by biochemical techniques. In this approach, a DNA-regulatory element that has been identified by the kinds of

mutational analyses described above is used to identify *cognate* proteins — those proteins that bind specifically to it. Two common techniques for detecting such cognate proteins are DNase I footprinting and the electrophoretic mobility shift assay.

DNase I footprinting takes advantage of the fact that when a protein is bound to a region of DNA, it protects that DNA sequence from digestion by nucleases. As illustrated in Figure 8-19, samples of a DNA fragment that has been labeled with a radioactive molecule at one end of one strand are digested under carefully controlled conditions in the presence and absence of a DNA-binding protein. Then the DNA is purified away from all of the protein, denatured and electrophoresed, and the resulting gel is subjected to autoradiography. The region protected by the bound protein appears as a gap, or *footprint*, in the array of bands resulting from digestion in the absence of the protein. When footprinting is performed with a DNA fragment containing a known transcription-control element, the appearance of a footprint indicates the presence of a transcription factor that binds that control element in the protein sample being assayed. Footprinting also identifies the specific DNA sequence to which the transcription factor binds.

EXPERIMENTAL FIGURE 8-19 DNase I footprinting reveals the region of a DNA sequence where a transcription factor binds. (a) A DNA fragment known to contain a transcription-control element is labeled at one end with $^{32}\mathrm{P}$ (red dot). Portions of the labeled DNA sample are then digested with DNase I in the presence and in the absence of protein samples containing a sequence-specific DNA-binding protein. DNase I hydrolyzes the phosphodiester bonds of DNA between the $3'$ oxygen on the deoxyribose of one nucleotide and the $5'$ phosphate of the next nucleotide. A low concentration of DNase I is used so that, on average, each DNA molecule is cleaved just once (vertical arrows). If the protein sample does not contain a protein that binds to a specific sequence in the labeled DNA, the DNA fragment is cleaved at multiple positions between the labeled and unlabeled ends of the original fragment, as in sample A (*left*). If the protein sample does contain such a protein, as in sample B (*right*), the protein binds to its cognate sequence in the DNA, thereby protecting a portion of the fragment from digestion. Following DNase treatment, the DNA is separated from protein, denatured to separate the strands, and electrophoresed. Autoradiography of the resulting gel detects only labeled strands and reveals fragments extending from the labeled end to the site of

cleavage by DNase I. Cleavage fragments containing the transcription-control element show up on the gel for sample A but are missing in sample B because the bound cognate protein has blocked cleavages within that sequence and thus production of the corresponding fragments. The missing bands on the gel constitute the footprint. (b) Footprints produced by increasing amounts of TBP (indicated by the triangle) and of TFIID on the strong adenovirus major late promoter.

[Part (b) Republished with permission from Cold Spring Harbor Laboratory Press, from Q. Zhou et al., 1992, "Holo-TFIID Supports Transcriptional Stimulation by Diverse Activators and from a TATA-Less Promoter," *Genes Dev.* **6**(10):1964–1974.]

For example, DNase I footprinting of the strong adenovirus late promoter shows a protected region over the TATA box when TBP is added to the labeled DNA before DNase I digestion (Figure 8-19b). DNase I does not digest all phosphodiester bonds in a duplex DNA at equal rate. Consequently, in the absence of added protein (lanes 1, 6, and 9), a particular pattern of bands is observed that depends on the DNA sequence and results from cleavage at some phosphodiester bonds and not others. However, when increasing amounts of TBP are incubated with the end-labeled DNA before digestion with DNase I, TBP binds to the TATA box, and when sufficient TBP is added to bind all the labeled DNA molecules, it protects the region between about −35 and −20 from digestion (lanes 2–5). In contrast, increasing amounts of TFIID (lanes 7 and 8) protect not only the TATA box region but also regions near −7 to +5, +10 to +15, and +20 from digestion, producing a footprint different from TBP's. Results such as this tell us that other subunits of TFIID (the TBP-associated

factors, or TAFs) also bind to the DNA in the region downstream from the TATA box.

The **electrophoretic mobility shift assay (EMSA)**, also called the *gel-shift* or *band-shift assay*, is more useful than the footprinting assay for quantitative analysis of DNA-binding proteins. In general, the electrophoretic mobility of a DNA fragment is reduced when it is complexed with protein, causing a shift in the location of the fragment band. EMSA can be used to detect a transcription factor in protein fractions incubated with a radiolabeled DNA fragment (the probe) containing a known control element (Figure 8-20). As the amount of transcription factor added to the binding reaction is increased, the more labeled probe is shifted to the position of the DNA-protein complex. The results indicate that the concentration of this specific DNA-binding protein was highest in fraction 8, lower in fraction 7, still lower in fraction 9, and undetectable by this assay in the other fractions eluted from the column.

EXPERIMENTAL FIGURE 8-20 The electrophoretic mobility shift assay can be used to detect transcription factors during purification. In this example, protein fractions separated by column chromatography were assayed for their ability to bind to a radiolabeled DNA-fragment probe containing a known regulatory element. An aliquot of the protein sample that had been loaded onto the column (ON) and successive column fractions (numbers) were incubated with the labeled probe. The samples were then electrophoresed under conditions that do not disrupt protein-DNA interactions. The free probe not bound to protein migrated to the bottom of the gel. A protein in fractions 7 and 8 bound to the probe (as did protein in the unfractionated sample in column ON), forming a DNA-protein complex that migrated more slowly than the free probe. These fractions are therefore likely to contain the regulatory protein being sought.

In the biochemical isolation of a transcription factor, an extract of cell nuclei is commonly subjected sequentially to several types of

liquid chromatography (see Chapter 3). Fractions eluted from the columns are assayed by DNase I footprinting or EMSA using DNA fragments containing an identified regulatory element (see Figure 8-17). Fractions containing a protein that binds to the regulatory element in these assays contain a putative transcription factor. A powerful technique that is commonly used for the final step in purifying transcription factors is *sequence-specific DNA affinity chromatography*, a particular type of affinity chromatography in which long DNA strands containing multiple copies of the transcription-factor-binding site are coupled to a column matrix.

Once a transcription factor has been isolated and purified, its partial amino acid sequence can be determined and used to clone the gene or cDNA encoding it, as outlined in Chapter 6. The isolated gene can then be used to test the ability of the encoded protein to activate or repress transcription in an in vivo transfection assay (Figure 8-21).

EXPERIMENTAL FIGURE 8-21 An in vivo transfection assay measures transcription activity to evaluate proteins believed to be transcription factors. The assay system requires two plasmids. One plasmid contains the gene encoding the putative transcription factor (protein X). The second plasmid contains a reporter gene (e.g., luciferase) and one or more binding sites for protein X. Both plasmids are simultaneously introduced into cells that lack the gene-encoding protein X. The production of reporter-gene RNA transcripts is measured; alternatively, the activity of the encoded protein can be assayed. If reporter-gene transcription is greater in the presence of the X-encoding plasmid than in its absence, then the protein is an activator; if transcription is less, then it is a repressor. By use of plasmids encoding a

mutated or rearranged transcription factor, important domains of the protein can be identified.

Activators Are Composed of Distinct Functional Domains

Studies with a yeast transcription activator called *Gal4* provided early insight into the domain structure of transcription factors. The gene encoding Gal4, which promotes expression of enzymes needed to metabolize galactose, was identified by complementation analysis of *gal4* mutants that cannot form colonies on an agar medium in which galactose is the only source of carbon and energy (see Chapter 6). Directed mutagenesis studies, like those described previously, identified UASs for the genes activated by Gal4 (see Figures 8-17). Each of these UASs was found to contain one or more copies of a 17-bp sequence called UAS_{GAL}. DNase I footprinting assays with recombinant Gal4 protein produced in *E. coli* from the yeast *GAL4* gene showed that Gal4 binds to UAS_{GAL} sequences. When a copy of UAS_{GAL} was cloned upstream of a TATA box followed by a β-galactosidase reporter gene, and that construct was introduced into yeast cells, expression of β-galactosidase was activated in galactose media in wild-type cells, but not in *gal4* mutants. These results showed that UAS_{GAL} is a transcription-control element activated by the Gal4 transcription factor in galactose media.

A remarkable set of experiments demonstrated that the Gal4 transcription factor is composed of separable functional domains: an N-terminal **DNA-binding domain**, which binds to specific DNA sequences, and a C-terminal **activation domain**, which interacts with other proteins to stimulate transcription from a nearby promoter (Figure 8-22). When the N-terminal DNA-binding domain of Gal4 was fused directly to various portions of its own C-terminal region, deleting internal sequences, the resulting truncated proteins retained the ability to stimulate expression of a reporter gene in an in vivo assay like that depicted in Figure 8-21. Thus the internal portion of the protein is not required for the functioning of Gal4 as a transcription factor. Similar experiments with another yeast activator, Gcn4, which regulates genes required for the synthesis of many amino acids, indicated that it contains a roughly 50–amino acid DNA-binding domain at its C-terminus and a roughly 20–amino acid activation domain near the middle of its sequence.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 8-22 Deletion mutants of the *GAL4* gene in yeast with a UAS_{GAL} reporter-gene construct demonstrate the separate functional domains in a transcription activator. (a) Diagram of DNA construct containing a *lacZ* reporter gene (encoding β-galactosidase) and TATA box ligated to UAS_{GAL}, a regulatory element that contains several Gal4-binding sites. The reporter-gene construct and DNA encoding wild-type or mutant (deleted) Gal4 were simultaneously introduced into mutant (*gal4*) yeast cells, and the activity of β-galactosidase expressed from *lacZ* was assayed. Activity should be high if the introduced *GAL4* DNA encodes a functional protein. (b) Schematic diagrams of wild-type Gal4 and various mutant forms. Small numbers refer to positions in the wild-type sequence. Deletion of 50 amino acids from the N-terminal end destroyed the ability of Gal4 to bind to UAS_{GAL} and to stimulate expression of β-galactosidase from the reporter gene. Proteins with extensive deletions from

the C-terminal end still bound to UAS_{GAL}. These results localize the DNA-binding domain to the N-terminal end of Gal4. The ability to activate β-galactosidase expression was not entirely eliminated unless somewhere between 126 and 189 or more amino acids were deleted from the C-terminal end. Thus the activation domain lies in the C-terminal region of Gal4. Proteins with internal deletions (*bottom*) were also able to stimulate expression of β-galactosidase, indicating that the central region of Gal4 is not crucial for its function in this assay. See J. Ma and M. Ptashne, 1987, *Cell* **48**:847; I. A. Hope and K. Struhl, 1986, *Cell* **46**:885; and R. Brent and M. Ptashne, 1985, *Cell* **43**:729.

Further evidence for the existence of distinct activation domains in Gal4 and Gcn4 came from experiments in which their activation domains were fused to a DNA-binding domain from an entirely unrelated *E. coli* DNA-binding protein. When these fusion proteins were assayed in vivo, they activated transcription of a reporter gene containing the cognate site for the *E. coli* protein. Thus functional transcription factors can be constructed from novel combinations of bacterial and eukaryotic protein domains.

Studies such as these have now been carried out with many eukaryotic transcription factors. The structural model of eukaryotic activators that has emerged from these studies is a modular one. Specifically, one or more activation domains are connected to a sequence-specific DNA-binding domain by flexible, intrinsically disordered protein domains (Figure 8-23). In some cases, amino acids included in the DNA-binding domain also contribute to transcriptional activation. As discussed in a later section, activation domains function by binding other proteins involved in both the

control of chromatin condensation and transcription. The presence of flexible, intrinsically disordered protein domains (see Figure 3-13) connecting the DNA-binding domain to the activation domains may explain why alterations in the spacing between control elements are so well tolerated in eukaryotic control regions. Thus even when the positions of transcription factors bound to DNA are shifted relative to each other, their activation domains may still be able to interact because they are attached to their DNA-binding domains through flexible protein regions. Also, as discussed in Section 8.4, some intrinsically disordered regions in transcription factors and other proteins involved in transcription interact through multiple low-affinity contacts to form *condensates* within the nucleus. These condensates concentrate proteins involved in transcription, increasing the rates with which they interact, thus greatly stimulating the rate of transcription.

FIGURE 8-23 Schematic diagrams illustrating the modular structure of eukaryotic transcription activators. Transcription factors may contain more than one activation domain but rarely contain more than one DNA-binding domain. Gal4 and Gcn4 are yeast transcription activators. The glucocorticoid receptor (GR) promotes transcription of target genes when certain hormones are bound to the C-terminal activation domain. SP1 binds to GC-rich promoter elements (e.g., GCGGCGCGGC) in a large number of mammalian genes.

Repressors Are the Functional Converse of Activators

Eukaryotic transcription is regulated by repressors as well as activators. For example, geneticists have identified mutations in yeast that result in continuously high expression of certain genes. This type of unregulated, abnormally high expression, called **constitutive** expression, results from the inactivation of a repressor that normally inhibits the transcription of these genes. Similarly, mutants of *Drosophila melanogaster* and *Caenorhabditis elegans* have been isolated that are defective in embryonic development because they express genes in embryonic cells where those genes are normally repressed. The mutations in these mutants inactivate repressors, leading to abnormal development.

Repressor-binding sites in DNA have been identified by systematic linker scanning mutation analyses similar to the one depicted in Figure 8-17. In this type of analysis, whereas mutation of an activator-binding site leads to decreased expression of the linked reporter gene, mutation of a repressor-binding site leads to increased expression of a reporter gene. The repressor proteins that bind such sites can be purified and assayed for their ability to bind to the repressing DNA-control element using the same biochemical techniques described earlier for activator proteins.

Eukaryotic transcription repressors are the functional converse of activators. They can inhibit transcription of a gene they do not normally regulate when their cognate binding sites are placed within tens of base pairs to many kilobases of the gene's transcription start site. Like activators, most eukaryotic repressors are modular proteins that have two functional domains: a DNA-binding domain and a **repression domain**. Like activation domains, repression domains continue to function when fused to another type of DNA-binding domain. If binding sites for this second DNA-binding domain are inserted within a few hundred base pairs of a promoter, expression of the fusion protein inhibits transcription from the promoter. Also like activation domains, repression domains function by interacting with other proteins, as discussed later in this chapter.

DNA-Binding Domains Can Be Classified into Numerous Structural Types

To activate or repress transcription, transcription factors must bind to the specific DNA sequences of transcription control regions via their DNA-binding domains. The DNA-binding domains of eukaryotic transcription factors are comprised of a variety of structural motifs that bind specific DNA sequences. The ability of DNA-binding proteins to bind to specific DNA sequences commonly

results from noncovalent interactions between atoms in an α helix in the DNA-binding domain and atoms on the edges of the bases within the major groove in the DNA. Ionic interactions between positively charged residues arginine and lysine and negatively charged phosphates in the sugar-phosphate backbone, and in some cases, interactions with atoms in the DNA minor groove, also contribute to binding.

The principles of specific protein-DNA interactions were first discovered during the study of bacterial repressors. Many bacterial repressors are dimeric proteins in which an α helix from each monomer inserts into the major groove in the DNA helix and makes multiple, specific interactions with the atoms there (Figure 8-24). This α helix is referred to as the *recognition helix* or *sequence-reading helix* because most of the amino acid side chains that contact bases in the DNA extend from this helix. The recognition helix, which protrudes from the surface of a bacterial repressor, is usually supported in the protein structure in part by hydrophobic interactions with a second α helix located just to the amino-terminal side of it. This entire structural element, which is present in many bacterial repressors, is called a *helix-turn-helix* motif (see Figure 8-24).

FIGURE 8-24 Interaction of bacteriophage 434 repressor with DNA. (a) Ribbon diagram of 434 repressor bound to its specific operator DNA. The recognition helices are green. The beginning of the α helix N-terminal to the recognition helix is yellow and the turn in the polypeptide backbone between the helices in the helix-turn-helix structural motif is red. (b) A space-filling model of the repressor-operator complex shows how the protein interacts intimately with one side of the DNA molecule over a length of 1.5 turns.

[Data from A. K. Aggarwal et al., 1988, *Science* **242**:899, PDB ID 2ori.]

There are a number of structural motifs in eukaryotic transcription factors that present an α helix to the major groove of DNA. Because most of these motifs have characteristic consensus–amino acid sequences, potential transcription factors can be recognized among the cDNA sequences from various tissues that have been characterized in humans and other species. Here we introduce several common classes of DNA-binding proteins whose three-dimensional structures have been determined. In all of these

examples, and in many other transcription factors, at least one α helix is inserted into the major groove of DNA. However, note that some transcription factors contain alternative structural motifs that interact with DNA (e.g., β strands and loops; see NFAT in Figure 8-28a as an example).

Homeodomain Proteins

Many eukaryotic transcription factors that function during development contain a conserved 60-residue DNA-binding motif, called a **homeodomain**, that is similar to the helix-turn-helix motif of bacterial repressors. These transcription factors were first identified in *Drosophila* mutants in which one body part was transformed into another during development (see Figure 8-2b). The conserved homeodomain sequence has also been found in vertebrate transcription factors, including those that have similar master-control functions required for the development of anatomical structures.

Zinc-Finger Proteins

The DNA-binding domain found most often in vertebrate genomes is called a **zinc finger**. The polypeptide chain in this structural domain is folded around a central Zn^{2+} ion, producing a compact domain from a relatively short length of polypeptide (∼25 amino acid residues). This structural motif was first recognized in DNA-binding

domains, but is now known to occur in other proteins that do not bind to DNA. Here we describe two of the several classes of zinc-finger motifs that have been identified in eukaryotic transcription factors.

The *C_2H_2 zinc finger* is the most common DNA-binding motif encoded in the human genome and the genomes of other vertebrates and is also common in multicellular plants. This motif has a 23–26-residue consensus sequence containing two conserved cysteine (C) and two conserved histidine (H) residues, whose side chains bind one Zn^{2+} ion (see Figure 3-7c). The name "zinc finger" was coined because a two-dimensional diagram of the structure resembles a finger. When the three-dimensional structure was solved, it became clear that the binding of the Zn^{2+} ion by the two cysteine and two histidine residues folds the relatively short polypeptide sequence into a compact domain, which can insert its α helix into the major groove of DNA. C_2H_2 zinc finger proteins contain at least two of these Zn-fingers, and many contain multiple C_2H_2 zinc fingers, which interact with successive groups of base pairs, within the major groove, as the protein wraps around the DNA double helix (Figure 8-25a).

FIGURE 8-25 Eukaryotic DNA-binding domains that use an α helix to interact with the major groove of specific DNA sequences. (a) The GL1 DNA-binding domain is monomeric and contains five C_2H_2 zinc fingers. The α helices are shown as cylinders, the Zn^{2+} ions as spheres. Finger 1 does not interact with DNA, whereas the other four fingers do. (b) The glucocorticoid receptor is a homodimeric C_4 zinc-finger protein. The α helices are shown as cylinders, the β strands as white arrows, and the Zn^{2+} ions as black spheres. Two α helices, one in each monomer, interact with the DNA. Like all C_4 zinc-finger homodimers, this transcription factor has twofold rotational symmetry. (c) In leucine-zipper proteins, basic residues in the extended α-helical regions of the monomers interact with the DNA backbone at adjacent sites in the major groove. The coiled-coil dimerization domain is stabilized by hydrophobic interactions between the monomers. (d) In bHLH proteins, the DNA-binding helices at the bottom (N-termini of the monomers) are separated by nonhelical loops from a leucine zipper–like region containing a coiled-coil dimerization domain.

[Part (a) Data from N. P. Pavletich and C. O. Pabo, 1993, *Science* **261**:1701. Part (b) Data from B. F. Luisi et al., 1991, *Nature* **352**:497. Part (c) Data from T. E. Ellenberger et al., 1992, *Cell* **71**:1223, PDB ID 1ysa. Part (d) Data from A. R. Ferre-D'Amare et al., 1993, *Nature* **363**:38, PDB ID 1an2.]

A second type of zinc-finger structure, designated the *C_4 zinc finger* (because it has four conserved cysteines in contact with the Zn^{2+}), is found in some 50 human transcription factors. The first members of this class were identified as specific intracellular high-affinity binding proteins, or "receptors," for steroid hormones, which led to the name *steroid receptor superfamily.* Because similar intracellular receptors for nonsteroid hormones were subsequently found, these transcription factors are now commonly called **nuclear receptors**. The characteristic feature of C_4 zinc fingers is the presence of two groups of four critical cysteines, one toward each end of the 55–56-residue domain.

Although the C_4 zinc finger was initially named by analogy with the C_2H_2 zinc finger, the three-dimensional structures of proteins containing these DNA-binding motifs were later found to be quite distinct. A particularly important difference between the two is that C_2H_2 zinc-finger proteins generally contain three or more repeating finger units and bind as monomers, whereas C_4 zinc-finger proteins generally contain only two finger units and generally bind to DNA as homodimers or heterodimers. Homodimers of C_4 zinc-finger DNA-binding domains have twofold rotational symmetry (Figure 8-25b).

Consequently, homodimeric nuclear receptors bind to consensus DNA sequences that are inverted repeats.

Leucine-Zipper Proteins

Another structural motif present in the DNA-binding domains of a large class of transcription factors contains the hydrophobic amino acid leucine at every seventh position in the sequence. These proteins bind to DNA as dimers, and mutagenesis of the leucines has shown that they are required for dimerization. Consequently, the name **leucine zipper** was coined to denote this structural motif of a coiled coil of two α helices.

The DNA-binding domain of the yeast Gcn4 transcription factor mentioned earlier is a leucine-zipper domain. X-ray crystallographic analysis of complexes between DNA and the Gcn4 DNA-binding domain has shown that the dimeric protein contains two extended α helices that grip the DNA molecule, much like a pair of scissors, at two adjacent sites in the major groove separated by about half a turn of the double helix (Figure 8-25c). The portions of the α helices contacting the DNA include positively charged (basic) residues that interact with phosphates in the DNA backbone and additional residues that interact with specific bases in the major groove.

Gcn4 forms dimers via hydrophobic interactions between the C-terminal regions of the α helices, forming a coiled-coil structure. This structure is common in proteins containing amphipathic α

helices in which hydrophobic amino acid residues are regularly spaced alternately three or four positions apart in the sequence, forming a stripe down one side of the α helix. These hydrophobic stripes make up the interacting surfaces between the α-helical monomers in a coiled-coil dimer (see Figure 3-7a).

Although the first leucine-zipper transcription factors to be analyzed contained leucine residues at every seventh position in the dimerization region, additional DNA-binding proteins containing other hydrophobic amino acids in these positions were subsequently identified. Like leucine-zipper proteins, they form dimers containing a C-terminal coiled-coil dimerization region and an N-terminal DNA-binding domain. The term *basic zipper (bZIP)* is now frequently used to refer to all proteins with these common structural features. Many basic-zipper transcription factors are heterodimers of two different polypeptide chains, each containing one basic-zipper motif.

Basic Helix-Loop-Helix (bHLH) Proteins

The DNA-binding domain of another class of dimeric transcription factors contains a structural motif that is very similar to the basic-zipper motif except that a nonhelical loop of the polypeptide chain separates two α-helical regions in each monomer (Figure 8-25d). Termed a **basic helix-loop-helix (bHLH)**, this motif was predicted from the amino acid sequences of these proteins, which contain an

N-terminal α helix with basic residues that interact with DNA, a middle loop region, and a C-terminal region, with hydrophobic amino acids spaced at intervals characteristic of an amphipathic α helix, that dimerizes into a coiled coil. As with basic-zipper proteins, different bHLH proteins can form heterodimers.

Structurally Diverse Activation and Repression Domains Regulate Transcription

Experiments with fusion proteins composed of the Gal4 DNA-binding domain and random segments of *E. coli* proteins demonstrated that a diverse group of amino acid sequences (∼1 percent of all *E. coli* sequences) can function as activation domains, even though they evolved to perform other functions. Many transcription factors contain activation domains marked by an unusually high percentage of particular amino acids. Gal4, Gcn4, and most other yeast transcription factors, for instance, have activation domains that are rich in acidic amino acids (aspartic and glutamic acids). These so-called *acidic activation domains* are generally capable of stimulating transcription in nearly all types of eukaryotic cells — fungal, animal, and plant cells. Activation domains from some *Drosophila* and mammalian transcription factors are glutamine-rich, and some are proline-rich; still others are rich in the closely related amino acids serine and threonine,

both of which have hydroxyl groups. However, some strong activation domains are not particularly rich in any specific amino acid.

Biophysical studies indicate that acidic activation domains have an unstructured, random-coil, intrinsically disordered conformation. These domains stimulate transcription when they are bound to a protein *co-activator*. The interaction with a co-activator causes the activation domain to assume a more structured α-helical conformation in the activation domain–co-activator complex. A well-studied example of a transcription factor with an acidic activation domain is the mammalian CREB protein, which is phosphorylated in response to increased levels of cAMP. This regulated phosphorylation is required for CREB to bind to its co-activator CBP (*C*REB *b*inding *p*rotein), resulting in the transcription of genes whose control regions contain a CREB-binding site (see Figure 15-24). When the phosphorylated random-coil activation domain of CREB interacts with CBP, it undergoes a conformational change to form two α helices linked by a short loop, which wrap around the interacting domain of CBP (Figure 8-26a).

FIGURE 8-26 Activation domains may be random coils until they interact with co-activator proteins or folded protein domains. (a) The activation domain of CREB (*c*yclic AMP *r*esponse *e*lement-*b*inding protein) is activated by phosphorylation at

serine 133. It is a random coil until it interacts with a domain of its co-activator, CBP (shown as a space-filling surface model with negatively charged regions in red and positively charged regions in blue). When the CREB activation domain binds to CBP, it folds into two amphipathic α helices. Side chains in the activation domain that interact with the surface of the CBP domain are labeled. (b) The ligand-binding activation domain of the estrogen receptor is a folded-protein domain. When estrogen is bound to the domain, the green α helix interacts with the ligand, generating a hydrophobic groove in the ligand-binding domain (dark brown helices), which binds an amphipathic α helix in a co-activator subunit (blue). (c) The conformation of the estrogen receptor in the absence of hormone is stabilized by binding of the estrogen antagonist tamoxifen. In this conformation, the green helix of the receptor folds into a conformation that interacts with the co-activator–binding groove of the active receptor, sterically blocking binding of co-activators.

[Part (a) Data from I. Radhakrishnan et al., 1997, *Cell* **91**:741, PDB ID 1kdx. Parts (b) and (c) Data from A. K. Shiau et al., 1998, *Cell* **95**:927, PDB ID 3erd and 3ert.]

Some activation domains are larger and more highly structured than acidic activation domains. For example, the ligand-binding domains of nuclear receptors function as activation domains when they bind their specific hormone ligand (Figure 8-26b, c). Binding of ligand induces a large conformational change in the nuclear receptor that allows the ligand-binding domain with bound hormone to interact with a short α helix in a co-activator; the resulting complex can then activate transcription of genes whose control regions bind the nuclear receptor.

Thus the acidic activation domain in CREB and the ligand-binding activation domains in nuclear receptors represent two structural extremes. The CREB acidic activation domain is an intrinsically

disordered random coil that folds into two α helices when it binds to the surface of a globular domain in a co-activator. In contrast, the nuclear-receptor ligand-binding activation domain is a structured globular domain that interacts with a short α helix in a co-activator, which probably is a random coil before it is bound. In both cases, however, specific protein-protein interactions between a co-activator and the activation domain permit the transcription factor to stimulate gene expression.

Currently, less is known about the structure of repression domains. The globular ligand-binding domains of some nuclear receptors function as repression domains in the absence of their specific hormone ligand. Like activation domains, repression domains may be relatively short, comprising 15 or fewer amino acids. Biochemical and genetic studies indicate that repression domains also mediate protein-protein interactions and bind to *co-repressor* proteins, forming a complex that inhibits transcription initiation by mechanisms that are discussed later in the chapter.

Transcription Factor Interactions Increase Gene-Control Options

Two types of DNA-binding proteins discussed previously — bZIP and bHLH proteins — often exist in alternative heterodimeric combinations of monomers. Other classes of transcription factors

not discussed here also form heterodimeric proteins. In some heterodimeric transcription factors, each monomer recognizes the same sequence. In these cases, the formation of alternative heterodimers does not increase the number of different sites on which the monomers can act, but rather allows the activation domains associated with each monomer to be brought together in alternative combinations that bind to the same site (Figure 8-27a). As we will see later, and in subsequent chapters, the activities of individual transcription factors can be regulated by multiple mechanisms. Consequently, a single bZIP- or bHLH-binding DNA-regulatory element in the transcription-control region of a gene may elicit different transcriptional responses depending on which bZIP or bHLH monomers are expressed in the cell and how their activities are regulated.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 8-27 Combinatorial possibilities due to formation of heterodimeric transcription factors. (a) In some heterodimeric transcription factors, the activation domain of each monomer recognizes the same DNA sequence. In the hypothetical example shown, transcription-factor monomers A, B, and C can all interact with one another, creating six different alternative combinations of activation domains that can all bind at the same site. Each composite binding site is divided into two half-sites, and each heterodimeric factor contains the activation domains of its two

constituent monomers. (b) When transcription-factor monomers recognize different DNA sequences, six alternative combinations of the transcription-factor monomers A, B, and C, each with a unique pair of activation domains, can bind to six different DNA sequences (sites 1–6). (c) Expression of an inhibitory factor (red) that interacts only with dimerization domain of A inhibits binding; hence transcriptional activation at sites 1, 4, and 5 is inhibited, but activation at sites 2, 3, and 6 is unaffected.

In some heterodimeric transcription factors, however, each monomer has a different DNA-binding specificity. The resulting combinatorial possibilities increase the number of potential DNA sequences that a family of transcription factors can bind. Three different transcription-factor monomers could theoretically combine to form six different homo- and heterodimeric transcription factors, as illustrated in Figure 8-27b. Four different monomers could form a total of ten dimeric factors; five monomers, sixteen dimeric factors; and so forth. In addition, inhibitory factors are known that bind to some bZIP and bHLH monomers, thereby blocking their binding to DNA. When these inhibitory factors are expressed, they repress transcriptional activation by the factors with which they interact (Figure 8-27c). Thus the rules governing the interactions of members of a heterodimeric transcription factor family are complex. This combinatorial complexity expands both the number of DNA sites from which these factors can activate transcription and the ways in which they can be regulated.

Similar combinatorial transcription regulation is achieved through the interaction of structurally unrelated transcription factors bound to closely spaced binding sites in DNA. An example is the interaction

of two transcription factors, NFAT and AP1, that bind to neighboring sites in a composite promoter-proximal element regulating the gene encoding interleukin-2 (IL-2). Expression of the *IL-2* gene is critical to the immune response, but abnormal expression of IL-2 can lead to autoimmune diseases such as rheumatoid arthritis (see Chapter 24). Neither NFAT nor AP1 binds to its site in the *IL-2* control region in the absence of the other protein. The affinities of these factors for these particular DNA sequences are too low for the individual factors to form a stable complex with DNA. However, when both NFAT and AP1 are present, protein-protein interactions between them stabilize the ternary complex composed of NFAT, AP1, and DNA (Figure 8-28a). Such *cooperative DNA binding* by various transcription factors results in considerable combinatorial complexity of transcriptional control. As a result, the 1600 or so transcription factors encoded in the human genome can bind to DNA through a much larger number of cooperative interactions, resulting in unique transcriptional control for each of the roughly 20,000 human genes. In the case of *IL-2*, transcription occurs only when NFAT is activated, which results in its transport from the cytoplasm to the nucleus, and when the genes encoding the two subunits of AP1 are activated at the same time. These two events are controlled by distinct signal transduction pathways (see Chapters 15 and 16), allowing stringent control of IL-2 expression.

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 8-28 Cooperative binding of two unrelated transcription factors to neighboring sites in a composite control element. (a) By themselves, both monomeric NFAT and heterodimeric AP1 transcription factors have low affinity for their respective binding sites in the *IL-2* promoter-proximal region. Protein-protein interactions between NFAT and AP1 add to the overall stability of the NFAT-AP1-DNA complex, so that the two proteins bind to the composite site cooperatively. (b) Cooperative DNA binding by dimeric SRF and monomeric SAP1 can occur when their binding sites are separated by 5–30 bp and when the SAP1 binding site is inverted because the domain of SAP1 that interacts with SRF is connected to the DNA-binding domain of SAP1 by a flexible linker region of the SAP1 polypeptide chain (dotted line).

[Part (a) Data from L. Chen et al., 1998, *Nature* **392**:42, PDB ID 1a02. Part (b) Data from M. Hassler and T. J. Richmond, 2001, *EMBO J*. **20**:3018, PDB ID 1hbx.]

Cooperative binding by NFAT and AP1 occurs only when their weak binding sites are positioned quite close to each other in DNA. The sites must be located at a precise distance from each other for effective binding. The requirements for cooperative binding are not so stringent in the case of some other transcription factors and transcription-control regions. For example, the *EGR-1* control region contains a composite binding site to which the SRF and SAP1 transcription factors bind cooperatively (Figure 8-28b). Because SAP1 has a long, flexible domain that interacts with SRF, the two proteins can bind cooperatively when their individual sites in DNA are separated by any distance up to about 30 bp or when the sites are inverted relative to each other.

Multiprotein Complexes Form on Enhancers

Recall that enhancers generally range in length from about 50 to 200 bp and include binding sites for multiple transcription factors. Let's look at the roughly 50-bp enhancer that regulates expression of β-interferon, an important protein in the defense against viral infections in vertebrates. The β-interferon enhancer binds several dimeric and single-subunit transcription factors. These can bind to specific transcription-factor-binding sites that constitute the enhancer (Figure 8-29). The term **enhanceosome** has been coined to describe large DNA-protein complexes, such as these, that assemble from transcription factors as they bind to the multiple binding sites in an enhancer.

FIGURE 8-29 Model of the enhanceosome that forms on the β-interferon enhancer. Two heterodimeric factors, Jun/ATF-2 and p50/RelA (NF-κB), and two copies each of the monomeric transcription factors IRF-3 and IRF-7, bind to the six overlapping binding sites in this enhancer. See D. Penne, T. Manniatis, and S. Harrison, 2007, *Cell* **129**:1111.

Because of the presence of flexible regions connecting the DNA-binding domains and activation or repression domains in transcription factors (see Figure 8-23), and because of the ability of interacting proteins bound to distant sites to produce loops in the DNA between their binding sites (Figure 8-30), considerable leeway in the spacing between regulatory elements in transcription-control regions is permissible. This tolerance for variable spacing between

binding sites for specific transcription factors, and between promoter binding sites for the general transcription factors and for Pol II, probably contributed to rapid evolution of gene control in eukaryotes. Transposition of DNA sequences and recombination between repeated sequences over evolutionary time probably created new combinations of control elements that were subjected to natural selection and retained if they proved beneficial. The latitude in spacing between regulatory elements probably allowed many more functional combinations to be subjected to this evolutionary experimentation than would be the case if constraints on the spacing between regulatory elements were strict, as is true for most genes in bacteria.

KEY CONCEPTS OF SECTION 8.3

Regulatory Sequences in Protein-Coding Genes and the Proteins Through Which They Function

- Expression of eukaryotic protein-coding genes is generally regulated through multiple protein-binding transcription-control regions that are located close to or distant from the transcription start site (see Figure 8-18).
- Promoters direct binding of RNA polymerase II to DNA, determine the site of transcription initiation, and influence the frequency of transcription initiation.
- Promoter-proximal elements occur within about 200 bp of a start site. Several such elements, containing 6–10 bp, may help regulate a particular gene.
- Enhancers, which contain multiple short control elements, may be located from 200 bp to tens of kilobases upstream or downstream from a promoter, within an intron, or downstream from the final exon of a gene.
- Promoter-proximal elements and enhancers are often cell-type-specific, functioning only in specific differentiated cell types.
- Transcription factors, which activate or repress transcription, bind to promoter-proximal regulatory elements and enhancers in eukaryotic DNA.
- Transcription activators and repressors are generally modular proteins containing a single DNA-binding domain and one or a few activation domains (for activators) or repression domains (for repressors). The different domains are frequently linked by flexible intrinsically disordered polypeptide regions (see Figure 8-23).
- Among the most common structural motifs found in the DNA-binding domains of eukaryotic transcription factors are the homeodomain, C_2H_2 zinc finger, basic zipper (leucine zipper), and basic helix-loop-helix (bHLH). All these and many other DNA-

binding motifs contain one or more α helices that interact with the major groove in their cognate site in DNA.

- Activation and repression domains in transcription factors exhibit a variety of amino acid sequences and three-dimensional structures. In general, these functional domains interact with co-activators or co-repressors, which are critical to the ability of transcription factors to modulate gene expression.
- The transcription-control regions of most genes contain binding sites for multiple transcription factors. Transcription of such genes varies depending on the particular repertoire of transcription factors that are expressed and activated in a particular cell at a particular time.
- Combinatorial complexity in transcriptional control results from alternative combinations of monomers that form heterodimeric transcription factors (see Figure 8-27) and from cooperative binding of transcription factors to composite control sites (see Figure 8-28).
- Binding of multiple transcription factors to multiple sites in an enhancer forms a large DNA-protein complex called an *enhanceosome* (see Figure 8-29).

8.4 Molecular Mechanisms of Transcription Repression and Activation

The repressors and activators that bind to specific sites in DNA and regulate expression of the associated protein-coding genes do so by three general mechanisms. First, these regulatory proteins act in concert with other proteins to modulate chromatin structure, inhibiting or stimulating the ability of general transcription factors to bind to promoters. Recall from Chapter 7 that the DNA in eukaryotic cells is not free, but is associated with a roughly equal mass of protein in the form of **chromatin**. The basic structural unit of chromatin is the **nucleosome**, which is composed of about 147 bp of DNA wrapped tightly around a disk-shaped core of *histone* proteins. Residues within the N-terminal region of each histone, and the C-terminal regions of histones H2A and H2B, called *histone tails,* extend from the surface of the nucleosome and can be reversibly modified (see Figure 7-26). Such modifications influence the relative condensation of chromatin and thus its accessibility to proteins required for transcription initiation. Second, activators and repressors interact with a large multiprotein complex called the *mediator of transcription complex,* or simply **Mediator**. This complex, in turn, binds to Pol II and directly regulates assembly of the preinitiation complex. In addition, some activation domains interact with TFIID-TAF subunits or other components of the preinitiation

complex, and these interactions contribute to preinitiation complex assembly. Finally, activation domains may also interact with the elongation factor P-TEFb (cyclin T-CDK9) and other as yet unknown factors to stimulate elongation by Pol II away from the promoter region.

In this section, we review the current understanding of how repressors and activators control chromatin structure and preinitiation complex assembly. In the next section of the chapter, we discuss how the concentrations and activities of activators and repressors themselves are controlled, so that gene expression is precisely attuned to the needs of the cell and organism.

Formation of Heterochromatin Silences Gene Expression at Telomeres, near Centromeres, and in Other Regions

Inactive genes in eukaryotic cells are often associated with **heterochromatin**, regions of chromatin that are highly condensed and stain darkly with DNA dyes (see Figure 7-28a). In contrast, most transcribed genes are located in lightly staining **euchromatin** (see Figure 7-28a). Regions of chromosomes near the centromeres and telomeres, as well as additional specific regions that vary in different cell types, are organized into heterochromatin. The DNA in

heterochromatin is less accessible to externally added proteins than is DNA in euchromatin and consequently is often referred to as "closed" chromatin. For instance, in an experiment described in Chapter 7, the DNA of inactive genes was found to be far more resistant to digestion by DNase I than the DNA of transcribed genes (see Figure 7-27).

Study of DNA regions in *S. cerevisiae* that behave like the heterochromatin of higher eukaryotes provided early insight into the **chromatin-mediated repression** of transcription. This yeast can grow either as haploid or diploid cells. Haploid cells exhibit one of two possible mating types, called **a** and α. Cells of different mating type can mate, or fuse, to generate a diploid cell (see Figure 1-24b). When a haploid cell divides by budding, the larger mother cell switches its mating type. Genetic and molecular analyses have revealed that three genetic loci on yeast chromosome III control the mating type of yeast cells (Figure 8-31). The central mating-type locus, termed *MAT* — the only one of the three that is actively transcribed — encodes transcription factors (**a**1, or α1 and α2) that regulate genes that determine the mating type. In any one cell, either an **a** or α DNA sequence is located at the *MAT* locus. The two additional loci, termed *HML* and *HMR*, near the left and right telomere, respectively, contain "silent" (nontranscribed) copies of the **a** or α genes. These sequences are transferred alternately from *HML*α or *HMR***a** into the *MAT* locus by a type of nonreciprocal recombination between homologous sequences during cell division.

When the *MAT* locus contains the DNA sequence from *HML*α, the cells behave as α cells. When the *MAT* locus contains the DNA sequence from *HMR***a**, the cells behave like **a** cells.

FIGURE 8-31 Arrangement of mating-type loci on chromosome III in the yeast *S. cerevisiae*. Silent (unexpressed) mating-type genes (either **a** or α) are located at the *HML* locus. The opposite mating-type gene is present at the silent *HMR* locus. When the α or **a** sequences are present at the *MAT* locus, they can be transcribed into mRNAs whose encoded proteins specify the mating-type phenotype of the cell. The silencer sequences near *HML* and *HMR* bind proteins that are critical for repression of these silent loci. Haploid cells can switch mating types in a process that transfers the DNA sequence from *HML* or *HMR* to the transcriptionally active *MAT* locus.

Our interest here is in how transcription of the silent mating-type genes at *HML* and *HMR* is repressed. If these genes are expressed, as they are in yeast mutants with defects in the repressing mechanism, both **a** and α proteins are expressed, causing the cells to behave like diploid cells, which cannot mate. The promoters and UASs controlling transcription of the **a** and α genes lie near the center of the DNA sequence that is transferred and are identical whether the sequences are at the *MAT* locus or at one of the silent

loci. This arrangement indicates that the function of the transcription factors that interact with these sequences must somehow be blocked at *HML* and *HMR*, but not at the *MAT* locus. This repression of the silent loci depends on **silencer sequences** located next to the region of transferred DNA at *HML* and *HMR* (see Figure 8-31). If the silencer is deleted, the adjacent locus is transcribed. Remarkably, any gene placed near the yeast mating-type silencer sequence by recombinant DNA techniques is repressed, or "silenced," even a tRNA gene transcribed by RNA polymerase III, which uses a different set of general transcription factors than RNA polymerase II uses, as discussed later.

Several lines of evidence indicate that repression of the *HML* and *HMR* loci results from a condensed chromatin structure that sterically blocks transcription factors from interacting with the DNA. In one telling experiment, the gene encoding an *E. coli* enzyme that methylates adenine residues in the sequence GATC was introduced into yeast cells under the control of a yeast promoter so that the enzyme was expressed. Researchers found that GATC sequences within the *MAT* locus and most other regions of the genome in these cells were methylated but not those within the *HML* and *HMR* loci. These results indicate that the DNA of the silent loci is inaccessible to the *E. coli* methylase, and presumably to proteins in general, including transcription factors and RNA polymerase. Similar experiments conducted with various yeast histone mutants indicated that specific interactions involving the

histone tails of H3 and H4 are required for formation of a fully repressed chromatin structure. Other studies have shown that the telomeres of every yeast chromosome also behave like silencer sequences. For instance, when a gene is placed within a few kilobases of any yeast telomere, its expression is repressed. In addition, this repression is relieved by the same mutations in the H3 and H4 histone tails that interfere with repression at the silent mating-type loci.

Genetic studies led to identification of several proteins, RAP1 and three SIR proteins, that are required for repression of the silent mating-type loci and the telomeres in yeast. RAP1 was found to bind within the DNA-silencer sequences associated with *HML* and *HMR* and to a sequence that is repeated multiple times at each yeast-chromosome telomere. Further biochemical studies showed that the SIR2 protein is a *histone deacetylase*; it removes acetyl groups on lysines of the histone tails. Furthermore, the RAP1 and SIR2, 3, and 4 proteins bind to one another, and SIR3 and SIR4 bind to the N-terminal tails of histones H3 and H4, which are maintained in a largely nonacetylated state by the deacetylase activity of SIR2. A series of experiments using fluorescence confocal microscopy on yeast cells either stained with fluorescent-labeled antibody to any one of the SIR proteins or RAP1 or hybridized to a labeled telomere-specific DNA probe revealed that these proteins form large, condensed telomeric nucleoprotein structures resembling the heterochromatin found in higher eukaryotes (Figure 8-32a, b, c).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 8-32 Antibody and DNA probes colocalize SIR3 protein with telomeric heterochromatin in yeast nuclei. (a) Confocal micrograph 0.3 μm thick through three diploid yeast cells, each containing 68 telomeres. Telomeres were labeled by hybridization to a fluorescent telomere-specific probe (yellow). DNA was stained red to reveal the nuclei. The 68 telomeres coalesce into a much smaller number of regions near the nuclear periphery. (b, c) Confocal micrographs of yeast cells labeled with a telomere-specific

hybridization probe (b) and a fluorescent-labeled antibody specific for SIR3 (c). Note that SIR3 is localized in the repressed telomeric heterochromatin. Similar experiments with RAP1, SIR2, and SIR4 have shown that these proteins also colocalize with the repressed telomeric heterochromatin. (d) Schematic model of the silencing mechanism at yeast telomeres. (*Top left*) Multiple copies of RAP1 bind to a simple repeated sequence at each telomere region that lacks nucleosomes. SIR3 and SIR4 bind to RAP1, and SIR2 binds to SIR4. SIR2 is a histone deacetylase that deacetylates the tails on the histones neighboring the repeated RAP1-binding site. (*Middle*) The hypoacetylated histone tails are also binding sites for SIR3 and SIR4, which in turn bind additional SIR2, deacetylating neighboring histones. Repetition of this process results in spreading of the region of hypoacetylated histones with associated SIR2, SIR3, and SIR4. (*Bottom*) Interactions between complexes of SIR2, SIR3, and SIR4 cause the chromatin to condense and several telomeres to associate, as shown in (a)–(c). The higher order chromatin structure generated sterically blocks other proteins from interacting with the underlying DNA. See M. Grunstein, 1997, *Curr. Opin. Cell Biol*. **9**:383.

[Parts (a)–(c) Data from M. Gotta et al., *1996, J. Cell Biol.* **134**:1349–1363; https://doi.org/10.1083/jcb.134.6.1349.]

Figure 8-32d depicts a model for the chromatin-mediated silencing at yeast telomeres based on these and other studies. Formation of heterochromatin at telomeres is nucleated by multiple RAP1 protein molecules bound to repeated sequences in a nucleosome-free region at the extreme end of a telomere. A network of protein-protein interactions involving telomere-bound RAP1, three SIR proteins (2, 3, and 4), and hypoacetylated histones H3 and H4 creates a nucleoprotein complex that includes several telomeres and in which the DNA is largely inaccessible to external proteins. Recall that nucleosomes in regions of heterochromatin have low levels of acetylation on lysines of the histone tails, while nucleosomes in euchromatin have histone tails that are acetylated on several lysines

(see Figure 7-28b). One additional protein, SIR1, is also required for silencing of the mating-type loci. It binds to the silencer regions associated with *HML* and *HMR* together with RAP1 and other proteins to initiate assembly of a similar multiprotein-silencing complex that encompasses *HML* and *HMR*.

An important feature of this model is the dependence of repression on *hypoacetylation* of the histone tails. This was demonstrated in experiments with yeast mutants in which lysines in histone N-termini were replaced with arginines, glutamines, or glycines. Arginine is positively charged, like lysine, but cannot be acetylated. Glutamine and glycine are neutral and simulate the neutral charge of acetylated lysine. Repression at telomeres and at the silent mating-type loci was defective in mutants with glutamine or glycine substitutions for lysine in the H3 and H4 histone tails. Repression was normal in mutants with arginine substitutions due to the positive charge that arginine provides to the histone tails. Further, acetylation of H3 and H4 lysines interferes with binding by SIR3 and SIR4 and consequently prevents repression at the silent loci and telomeres. Finally, chromatin immunoprecipitation experiments (see Figure 8-12a) using antibodies against acetylated lysines at specific positions in the histone N-terminal tails (see Figure 8-26a) confirmed that histones in repressed regions near telomeres and at the silent mating loci are hypoacetylated but become hyperacetylated in *sir* mutants when genes in these regions are derepressed.

Repressors Can Direct Histone Deacetylation at Specific Genes

The importance of **histone deacetylation** in chromatin-mediated gene repression was further supported by studies of eukaryotic repressors that regulate genes within chromosome arms, distant from telomeres and centromeres. These repressor proteins act in part by causing deacetylation of histone tails in nucleosomes that encompass the TATA box and promoter-proximal region of the genes they repress. In vitro studies have shown that when promoter DNA is part of a nucleosome with nonacetylated histones, the general transcription factors cannot bind to the TATA box and promoter-proximal region. In nonacetylated histones, the N-terminal lysines are positively charged and may interact with phosphates in the DNA backbone. Nonacetylated histone tails also interact with neighboring histone octamers and other chromatin-associated proteins, favoring the folding of chromatin into condensed regions (see Figures 7-24b and 7-27a). The net effect is that general transcription factors cannot assemble into a preinitiation complex on a promoter associated with hypoacetylated histones. In contrast, binding of general transcription factors is repressed much less by histones with hyperacetylated tails, in which the positively charged lysines are neutralized and electrostatic interactions within chromatin are eliminated.

The connection between histone deacetylation and repression of transcription at specific yeast promoters became clearer when the cDNA encoding a human histone deacetylase was found to have high homology to the yeast *RPD3* gene, known to be required for the normal repression of a number of yeast genes. Further work showed that the yeast Rpd3 protein has histone deacetylase activity. The ability of Rpd3 to deacetylate histones at a number of promoters depends on two other proteins: Ume6, a repressor that binds to a specific upstream regulatory sequence (URS1), and Sin3, which is part of a large multiprotein complex called *Rpd3L* that also contains Rpd3 (Figure 8-33a). Sin3 also binds to the repression domain of Ume6, thus positioning the Rpd3 histone deacetylase in the complex so that it can interact with nearby promoter-associated nucleosomes and remove acetyl groups from histone-tail lysines. Additional experiments, using the chromatin immunoprecipitation technique outlined in Figure 8-12a and antibodies to specific histone acetylated lysines, demonstrated that in wild-type yeast, one or two nucleosomes in the immediate vicinity of Ume6-binding sites are hypoacetylated. These sites include the promoters of genes repressed by Ume6. In *sin3* and *rpd3* deletion mutants, not only were these promoters derepressed, but the nucleosomes near the Ume6-binding sites were hyperacetylated. All of these findings provide considerable support for the model of repressor-directed deacetylation shown in Figure 8-33a.

FIGURE 8-33 Proposed mechanism of histone deacetylation and hyperacetylation in yeast transcriptional control. (a) Repressor-directed deacetylation of histone N-terminal tails. The DNA-binding domain (DBD) of the repressor Ume6 interacts with a specific upstream control element of the genes it regulates, called *URS1*. The Ume6 repression domain (RD) binds Sin3, a subunit of a multiprotein complex that includes Rpd3, a histone deacetylase. Deacetylation of histone N-terminal tails on nucleosomes in the region of the Ume6-binding site inhibits binding of general transcription factors at the TATA box, thereby repressing gene expression. (b) Activator-directed hyperacetylation of histone N-terminal tails. The DNA-binding domain of the activator Gcn4 interacts with specific upstream activating sequences (UAS) of the genes it regulates. The Gcn4 activation domain (AD) then interacts with a

multiprotein histone acetylase complex that includes the Gcn5 catalytic subunit. Subsequent hyperacetylation of histone N-terminal tails on nucleosomes in the vicinity of the Gcn4-binding site facilitates access by the general transcription factors required for initiation. Repression and activation of many genes in higher eukaryotes occur by similar mechanisms.

In yeast, the Sin3-Rpd3 complex (Rpd3L) functions as a **co-repressor**. Co-repressor complexes containing histone deacetylases have also been found associated with many repressors from mammalian cells (see Repressors Are the Functional Converse of Activators). Some of these complexes contain the mammalian homolog of Sin3 (mSin3), which interacts with the repression domain of repressors, as in yeast (see Figure 8-33a). Other histone deacetylase complexes identified in mammalian cells contain additional or different subunits that bind the repression domains of other eukaryotic repressors. These various repressor–co-repressor combinations mediate histone deacetylation at specific promoters by a mechanism similar to the yeast mechanism (see Figure 8-33a). In addition to repressing transcription through the formation of closed chromatin structures, some repression domains have also been found to inhibit the assembly of preinitiation complexes in experiments with purified general transcription factors in the absence of histones. This activity probably also functions in vivo, contributing to the repression of transcription by these repression domains.

Activators Can Direct Histone Acetylation at Specific Genes

Just as repressors function through co-repressors that bind to their repression domains, the activation domains of DNA-binding activators function by binding multisubunit **co-activator** complexes. One of the first co-activator complexes to be characterized was the yeast *SAGA complex*, which functions with the Gcn4 and Gal4 activator proteins described in Section 8.3. Early genetic studies indicated that full activity of the Gcn4 activator required a protein called *Gcn5*. The clue to Gcn5's function came from biochemical studies of a *histone acetylase* purified from the protozoan *Tetrahymena*, the first histone acetylase to be purified. Sequence analysis revealed homology between the *Tetrahymena* protein and yeast Gcn5, which was soon shown to have histone acetylase activity as well. Further genetic and biochemical studies revealed that Gcn5 is one subunit of the SAGA multiprotein co-activator complex. Another subunit of this histone acetylase complex binds to activation domains in multiple yeast activator proteins, including Gcn4. The model shown in Figure 8-33b is consistent with the observation that nucleosomes near the promoter region of a gene regulated by the Gcn4 activator are specifically hyperacetylated compared with most histones in the cell. This activator-directed hyperacetylation of nucleosomes near a promoter region facilitates binding of other proteins required for transcription initiation.

In addition to leading to the decondensation of chromatin, the acetylation of specific histone lysines generates binding sites for proteins containing **bromodomains**. A bromodomain is a sequence of about 110 amino acids that folds into a domain, which binds acetylated lysine. Bromodomains are found in several chromosome-associated proteins that contribute to transcriptional activation. For example, a subunit of the general transcription factor TFIID contains two bromodomains, which bind with high affinity to acetylated nucleosomes. Recall that TFIID binding to a promoter initiates assembly of an RNA polymerase II preinitiation complex (see Figure 8-13). Nucleosomes at promoter regions of virtually all active genes have acetylated lysines in their H3 and H4 histone tails.

A similar activation mechanism operates in higher eukaryotes. Mammalian cells contain multisubunit histone acetylase co-activator complexes that are homologous to the yeast SAGA complex. Mammalian cells also express two related 300-kDa, multidomain proteins called *CBP* and *p300*, which acetylate histone tail lysines. As noted earlier, one domain of CBP binds the phosphorylated acidic activation domain in the CREB transcription factor (Figure 8-26a). Other domains of CBP interact with activation domains in other activators. CBP also has histone acetylase activity and the ability to associate with additional multisubunit histone acetylase complexes. CREB and many other mammalian activators function in part by directing CBP and p300 and their associated histone acetylase complexes to specific nucleosomes, where they

acetylate histone tails, thereby facilitating the interaction of general transcription factors with promoter DNA.

Chromatin-Remodeling Complexes Help Activate or Repress Transcription

In addition to histone acetylase complexes, multiprotein *chromatin-remodeling complexes* are required for activation at many promoters. The first of these complexes to be characterized was the yeast **SWI/SNF chromatin-remodeling complex**. One of the SWI/SNF subunits has homology to DNA helicases, enzymes that use energy from ATP hydrolysis to disrupt interactions between base-paired nucleic acids or between nucleic acids and proteins. The SWI/SNF complex is thought to pump or push DNA into the nucleosome so that DNA bound to the surface of the histone octamer transiently dissociates from the surface and translocates, causing the nucleosomes to slide along the DNA. This chromatin remodeling facilitates binding of transcription factors to specific DNA sequences in chromatin. Many activation domains bind to *chromatin-remodeling complexes*, which stimulate in vitro transcription from chromatin templates. Thus the SWI/SNF complex represents another type of co-activator complex. The experiment shown in Figure 8-34 demonstrates dramatically how an activation domain can cause decondensation of a region of chromatin. This decondensation

results from association of the activation domain with chromatin-remodeling and histone acetylase complexes.

EXPERIMENTAL FIGURE 8-34 Expression of fusion proteins demonstrates chromatin decondensation in response to an activation domain. A cultured hamster cell line was engineered to contain multiple copies of a tandem array of *E. coli lac* operator sequences integrated into a chromosome in a region of heterochromatin. (a) When an expression vector for the *lac* repressor (LacI) was transfected into these cells, *lac* repressor bound to the *lac* operator sites could be visualized in a region of condensed chromatin using an antibody against the *lac* repressor (red). DNA was visualized by staining with DAPI (blue), revealing the nucleus. A diagram of condensed chromatin is shown below. (b) When LacI fused to an activation domain was transfected into these cells, staining as in (a) revealed that the activation domain causes this region of chromatin to decondense into a thinner

chromatin fiber that fills a much larger volume of the nucleus. A diagram of a region of decondensed chromatin with bound LacI fusions to the VP16 activation domain (AD) and associated chromatin remodeling and histone acetylase complexes is shown below.

[From T. Tumbar, G. Sudlow, and A. S. Belmont, 1999, *J. Cell. Biol.* **145**(7):1341–1354: https://doi.org/10.1083/jcb.145.7.1341]

Chromatin-remodeling complexes are required for many processes involving DNA in eukaryotic cells, including transcriptional control, DNA replication, recombination, and DNA repair. Several types of chromatin-remodeling complexes are found in eukaryotic cells, all with homologous DNA helicase domains. SWI/SNF complexes and related chromatin-remodeling complexes in multicellular organisms contain subunits with bromodomains that bind to acetylated histone tails. Consequently, SWI/SNF complexes continue to associate with activated, acetylated regions of chromatin, presumably maintaining them in a decondensed conformation. Chromatin-remodeling complexes can also participate in transcriptional repression. These complexes bind to the repression domains of repressors and contribute to repression, presumably by folding chromatin into condensed structures. Much remains to be learned about how this important class of proteins alters chromatin structure to influence gene expression and other processes.

Pioneer Transcription Factors Initiate the Process of Gene Activation During

Cellular Differentiation

As cells differentiate during embryogenesis and during differentiation from stem cells in adult organisms (see Chapter 22), many of the genes induced during the process are initially in repressed regions of heterochromatin in undifferentiated progenitor cells. Activation of these genes requires that the chromatin environment of their transcription-control regions become decondensed so that transcription factors can bind to enhancers and promoter-proximal control elements and so that the general transcription factors and Pol II can bind to promoters. In many cases, this decondensation is initiated by special *pioneer transcription factors* that can bind to their cognate binding sites in DNA even when those sites are within repressed heterochromatic regions of chromatin. These pioneer transcription factors bind to the surface of both the DNA and the histones in a nucleosome, and in some cases, such as for Sox2, use the binding energy to begin to unwrap the DNA from the nucleosome surface (Figure 8-35). This allows these pioneer factors to bind to their specific binding sites while the DNA is wrapped around a histone octamer with the opposite side of the DNA against the surfaces of histones.

FIGURE 8-35 Structure of the Sox11-nucleosome complex. Like Sox2, the closely related transcription factor Sox11 can bind its cognate-binding sites even when they are wrapped around the surface of a nucleosome. *Left:* Model of a nucleosome with two Sox11-binding sites, one inside the beginning of the DNA 1 2/3 wraps around the surface of the nucleosome, and the other near the end of the DNA wrap around the nucleosome. Histone α helices are shown as cylinders with H2A subunits yellow; H2Bs red; H3s blue; and H4s green. *Right:* When Sox11 binds its two DNA-binding sites in this nucleosome, it unwinds the DNA from the surface of the nucleosome, making it available for interacting with other proteins.

An example of pioneer transcription factors that activate transcription from a promoter in condensed chromatin involves the liver-specific gene *Alb1*, encoding serum albumin, a major constituent of blood serum that is secreted into the blood by hepatocytes, the major cell type in the liver. In the developing mouse, the FoxA and GATA-4 or GATA-6 transcription factors are the first to bind to an *Alb1* enhancer in undifferentiated gut endodermal cells destined to develop into the liver. FoxA has a *winged helix* DNA-binding domain that binds to one side of the DNA helix containing the FoxA-binding site. GATA factors are also able to bind to their specific sites in DNA when those sites are included in nucleosomal DNA wrapped around a histone octamer. The FoxA and GATA-4/6

activation domains may then interact with chromatin remodeling complexes and histone acetylase complexes to decondense the chromatin of the 120-bp *Alb1* enhancer, allowing the observed subsequent binding of four additional transcription factors in the nascent liver bud that develops later.

The Mediator Complex Forms a Molecular Bridge Between Activation Domains and Pol II

Once the interaction of activation domains with histone acetylase complexes and chromatin-remodeling complexes decondense the chromatin of a promoter region to an "open" structure that allows the binding of general transcription factors, activation domains of the transcription factors bound to DNA control elements interact with another multisubunit co-activator complex, the Mediator complex (Figure 8-36). Activation domain–Mediator interactions stimulate assembly of a preinitiation complex on a promoter. Recent cryoelectron microscopy studies show that the head and middle domains of the Mediator complex interact directly with Pol II. Several Mediator subunits bind to activation domains in various activator proteins. Thus Mediator can form a molecular bridge between an activator bound to its cognate site in DNA and Pol II bound to a promoter.

Mediator Complex." *Cell*, **157**(6): 1430–1444; permission conveyed through Copyright Clearance Center, Inc.]

Experiments with temperature-sensitive yeast mutants indicate that some Mediator subunits are required for transcription of virtually all yeast genes. These subunits help maintain the overall structure of the Mediator complex or bind to Pol II. In contrast, other Mediator subunits are required for activation or repression of specific subsets of genes. RNA-seq analysis (see Chapter 6) has been used to examine gene expression in yeast mutants with defects in nonessential Mediator subunits. Results indicate that each mutation influences transcription of 3–10 percent of all genes, meaning that the deletion either increases or decreases mRNA expression by a factor of twofold or more. In many cases, these Mediator subunits interact with specific activation domains. Thus when one Mediator subunit is defective, transcription of genes regulated by activators that bind to that subunit is severely depressed, but transcription of other genes is unaffected. Recent cryoelectron microscopy studies suggest that when activation domains interact with Mediator, the head, middle, and tail domains depicted in Figure 8-36b rotate relative to one another, creating a binding surface for RNA polymerase II. The polymerase-Mediator complex is referred to as the *holoenzyme*. The surfaces of the polymerase that interact with general transcription factors in the preinitiation complex (see Figure 8-13) remain exposed in the proposed model of the polymerase-Mediator complex.

The various experimental results indicating that individual Mediator subunits bind to specific activation domains suggest that multiple activators may influence transcription from a single promoter by interacting with a Mediator complex simultaneously or in rapid succession (Figure 8-37). Activators bound at enhancers or promoter-proximal elements can interact with Mediator associated with a promoter because chromatin, like DNA, is flexible and can form a loop, bringing the regulatory regions and the promoter close together (see Figure 8-30). The multiprotein complexes that form on eukaryotic promoters may comprise more than 100 polypeptides with a total mass of 3–5 megadaltons (MDa), which is as large as a ribosome.

FIGURE 8-37 Model of several DNA-bound activators interacting with a single Mediator complex. The ability of different Mediator subunits to interact with specific

activation domains may contribute to the integration of signals from several activators at a single promoter. See the text for discussion.

Transcriptional Condensates Greatly Increase the Rate of Transcription Initiation

Recently developed high resolution microscopic methods have revealed that proteins involved in transcription, such as Mediator, often co-localize in nuclei in puncta that are on the order of 0.5–0.1 μm in diameter — far larger than the diameter of a chromatin fiber. BRD4, a protein with four bromodomains that stimulates transcription elongation in promoter proximal regions where histones are highly acetylated, also forms similar puncta in vivo (Figure 8-38a). These regions of high protein concentrations contain hundreds to thousands of Mediator and BRD4 molecules. The punctate structures are not delimited by a membrane but are continuous with the surrounding nucleoplasm. Their formation is dependent on intrinsically disordered regions (IDRs) of nuclear proteins, including transcriptional activators, repressors, and co-activators (see Figure 8-23). Multiple short regions of polypeptide in these IDRs form weak interactions with short peptides in the IDRs of other nuclear proteins, causing what is referred to as “condensation” of multiple proteins into a “transcriptional condensate” (diagrammed in Figure 8-38b). These interactions are transient, but

the large number of these possible multivalent interactions causes the proteins to associate in a liquid-like state. Consequently, the process that forms these protein concentrates has been called a "liquid-liquid phase separation."

EXPERIMENTAL FIGURE 8-38 Phase separation of co-activators compartmentalizes and concentrates the transcription apparatus. (a) Immunofluorescence (IF) imaging of BRD4 and MED1 in mouse embryonic stem cells (mESCs). Fluorescence signal is shown alone (*left*) and merged with Hoechst stain for DNA (*right*). (b) Super-enhancers are clusters of enhancers (red) bound by master transcription factors (grey ovals) that concentrate high densities of co-activators (blue circles) and the transcription apparatus to drive robust expression of genes that play prominent roles in cell identity. This is achieved by the phase separation of co-activators, which is driven in part by high-valency and low-affinity interactions of intrinsically disordered regions (blue lines). (c) The indicated mEGFP or mCherry fusion proteins were mixed at 10 mM each in a buffer containing 10 percent Ficoll-400 and 125 mM NaCl. Indicated fluorescence channels are presented for each mixture. Illustrations summarizing results are shown on the right.

It has been possible to observe and study the formation of these protein condensates in vitro with purified proteins. Figure 8-38c shows an experiment with a purified fusion protein consisting of an ~200 amino acid–serine-rich IDR in the largest subunit of Mediator (MED1) fused to the red fluorescent protein called *mCherry* to allow the fusion protein to be detected by fluorescence microscopy. When incubated along with green-fluorescent protein that was not fused to an IDR in a buffer that promotes protein condensation, the mCherry-MED1-IDR became concentrated in droplets similar in size to the condensates observed in vivo (Figure 8-38c, *top*), while GFP was not concentrated in the droplets. On the other hand, when the same mCherry-MED1-IDR fusion protein was incubated with GFP

that was fused to an IDR from BRD4, the two fusion proteins were included in the same droplets (Figure 8-38c, *bottom*). This result shows that proteins with different IDRs can be concentrated in the same protein condensates. Further immunofluorescent staining has shown that condensates formed in a nuclear extract visualized with GFP-BRD4 and GFP-MED1 as in Figure 8-38a also contain hundreds to thousands of copies of many other proteins involved in transcription including RNA polymerase II with a hypo-phosphorylated CTD, the form of Pol II that can assemble into a preinitiation complex (see Figure 8-13). When IDRs required for formation of transcriptional condensates are deleted from an activator, the transcriptional activation function of the mutant activator is greatly diminished.

Super-Enhancers

Characterization of all the enhancers in cultured mammalian cells revealed that a small fraction of them are associated with regions containing multiple, closely spaced enhancers associated with highly acetylated histones over a region of 10 or more kilobases. These regions termed *super-enhancers* include ∼1.5–4 percent of all enhancers, depending on the cell type. Unlike typical enhancers, super-enhancers contain longer regions of DNA bound by transcription factors and their associated co-activators. This long region of bound transcription factors, many with IDRs, promotes the formation of transcriptional condensates on super-enhancers.

This leads to concentrations of proteins involved in transcription initiation within the condensate that are twenty- to a hundredfold higher than in other regions of the nucleoplasm, resulting in a huge increase in the rate of assembly of the multicomponent preinitiation complex, contributing greatly to the high rate of transcription induced by super-enhancers.

Super-enhancers often activate key cell identity genes expressed at high level that are important for normal mammalian development. For example, in fibroblasts, which secrete extremely high levels of collagens to provide tensile strength and flexibility to the extracellular matrix (see Chapter 20), a super-enhancer of ∼30–50 kb forms over the collagen 1A1 gene (*COL1A1*) and its upstream region (Figure 8-39a). The closely related histone acetylase co-activators p300 and CBP associate with chromatin throughout this region, presumably by interacting with multiple activators bound to their specific cognate-binding sequences. CBP/p300 acetylate histone H3 lysines (K in the one letter amino acid code) at positions 18 and 27. Acetylation at H3K27 was detected by chromatin immunoprecipitation with antibodies specific for H3 acetylated at K27 (Figure 8-39a, *top*). The length of the acetylated region associated with *COL1A1* was much longer than other regions of H3K27ac in this region. In contrast to fibroblasts, which express high levels of COL1A1, airway epithelial cells do not express high levels of COL1A1 and do not form a super-enhancer over the *COL1A1* gene (Figure 8-39a, *top*). Rather, in these epithelial cells, a super-

enhancer encompassing a 13-kb region of chromatin formed over the *KRT5* gene, resulting in high level expression of this protein that gives tensile strength and flexibility to a sheet of epithelial cells (see Chapter 20). A broad region of H3K27 acetylation was also associated with the *KRT6A* gene, expressed at lower but still substantial level in these cells, and small peaks of H3K27ac were associated with the *KRT6B* and *KRT6C* genes expressed at low level. None of the other keratin genes in this gene cluster were expressed in these cells, and consistently, they did not have peaks of H3K27ac associated with their TSSs, indicating that these promoters were not active in these cells (Figure 8-39b).

EXPERIMENTAL FIGURE 8-39 The COL1A1 and KRT 5 and 6A super-enhancers. (a) *Bottom:* Map of genes on human chromosome 17 between 48,200,000 and 48,400,000 base pairs from the left end, represented by the horizontal line demarcated in 50,000 base-pair intervals. Genes transcribed to the right are represented above the line; genes transcribed to the left, below the line. Exons are represented by vertical lines, with arrowheads indicating the $3'$ exon. Dashed vertical lines indicate the positions of transcription start sites (TSS) for genes expressed in airway epithelial cells. *Top:* Chromatin immunoprecipitation data (see Figure 8-12) for histone H3 lysine 27 acetylation (H3K27ac) from cultured human fibroblasts or airway epithelial cells, as indicated at the left. The data is reported as the number of times a sequence in each 50-bp interval along the chromosome was observed in cross-

linked chromatin fragments immunoprecipitated with antibody specific for an H3 peptide acetylated at lysine 27. Note that most peaks of H3K27ac were <5 kb in length. In contrast, COL1A1 is associated with a much longer, $\sim 30–50$-kb region of chromatin extensively acetylated on H3K27. This unusually long region of H3K27ac identifies this as a super-enhancer. (b) *Bottom:* Map of genes on human chromosome 12 between 52,800,000 and 53,000,000 base pairs from the left end. Dashed vertical lines indicate positions of TSSs for genes expressed in fibroblasts. *Top:* Chromatin immunoprecipitation data for histone H3K27ac from cultured human fibroblasts or airway epithelial cells.

[Data from R. Ferrari et al., 2014, *Cell Host Microbe* **16**:663–676.]

In situ hybridization experiments have shown that transcriptional condensates (see Figure 8-38a) associate with the super-enhancers that are active in a particular cell type. Presumably, the high concentration of proteins involved in transcription initiation within these transcriptional condensates results in the very high rates of transcription initiation associated with super-enhancers.

Transcription Occurs in Bursts

High-resolution video microscopy recently revealed that many genes expressed at high level are not continuously transcribed at high rates. Rather, transcription initiation from highly transcribed genes occurs in bursts of multiple initiation events separated by periods of no transcription between transcriptional bursts. This was observed in *Drosophila* embryos containing constructs of reporter genes attached to multiple copies of engineered stem loops in their 5′-untranslated sequence. The stem loops bind to bacteriophage coat

proteins with very high affinity and specificity. In the experiment presented in Figure 8-40, 24 copies of the binding site for the bacteriophage MS2-coat protein were inserted immediately downstream of the promoter region of the *Drosophila snail (sna)* gene, which is expressed in the early *Drosophila* embryo. When transgenic flies were generated containing this reporter inserted into one site on one chromosome, no expression of the transgene was detected. But transcription was detected when the inserted DNA contained an enhancer downstream of the reporter gene, an enhancer that activates expression of *sna* in the early *Drosophila* embryo (Figure 8-40b). Transcription was detected by expressing MS2-coat protein fused to GFP (green fluorescent protein) in the same cells in which the reporter gene construct was inserted. When the 5′-end of the reporter gene was transcribed, MS2-coat protein-GFP bound to the 24 MS2-coat protein-binding sites, generating a signal that was visible by confocal fluorescence microscopy (Figure 8-40a). A video of images of the embryo during the 14th nuclear cycle (∼60 min long) revealed one region of GFP fluorescence in each cell at the site of the transcribed, inserted reporter gene. But the intensity of the GFP signal in each cell was not continuous. Rather, the intensity of each spot of fluorescence increased and decreased over several minutes (Figure 8-40d and associated movie, whose link is in the Figure 8-40 legend).

EXPERIMENTAL FIGURE 8-40 Highly expressed genes are transcribed in bursts. (a) Transcriptional focus detected by binding of MS2-coat protein-yellow fluorescent protein (MCP-YFP) to the 24 coat protein binding sites at the 5′-end of the RNA transcribed from the reporter gene. (b) *Top:* Schematic representation of reporter gene containing 100-bp of the *sna* promoter spanning the transcription start site and 24× MS2 RNA stem loops within the 5′ UTR. The strong 1.5-kb *sna* "shadow" enhancer was placed 7.5 kb downstream.

Bottom: Trace of fluorescence intensity over time of signal in an individual nucleus. (c) Same as part (b) but with the *rho* NE enhancer substituted for the *sna* shadow enhancer. (d) Frames from movies of transcriptional bursting. "$3'$ *sna* shadow" (*right*) shows yellow fluorescence bursts (which appear green) in living *Drosophila* embryos in which all cells have the integrated reporter gene indicated in part (b). The time shown (23 minutes and 20 seconds) is the time elapsed since the 14th nuclear division. "Enhancer deletion" (*left*) is the reporter construct in (b) but with no enhancer inserted. "$5'$ *sna* shadow" (*middle*) has the *sna* shadow enhancer inserted 1 kb upstream of the *sna* promoter. To watch the movie, go to https://www.cell.com/cms/10.1016/j.cell.2016.05.025/attachment/ 2184326d-3b6c-47d6-8121-c00c36c3ebeb/mmc2. The movie starts at nuclear cycle (nc) 14 of embryogenesis and continues until gastrulation. The cells also express a fusion of RFP to histone H2A shown in blue, as a marker for the nucleus. Anterior is to the left and ventral is facing up.

[Republished with permission by Elsevier, from T. Fukaya, B. Lim, and M. Levine (2016) Enhancer Control of Transcriptional Bursting. *Cell* **166** (2): 358–368; permission conveyed through Copyright Clearance Center, Inc.]

The intensity of a single fluorescent focus in one nucleus was plotted versus time for this construct with the strong *sna* "shadow" enhancer and for a second construct with the weaker *rho* NEE enhancer (Figures 8-40b and c, respectively). Bursts of fluorescence were observed extending for variable periods of time averaging $\sim$4 min (the width of the peaks). Based on the fluorescence intensity, each burst is thought to have resulted from 20–100 transcription initiation events over the $\sim$4 min period of a single transcriptional burst. For the construct with the strong *sna* shadow enhancer, bursts occurred frequently; for the construct with the weaker *rho* NEE enhancer, bursts of approximately the same height resulting from

20–100 transcription initiations also were observed, but the bursts occurred less frequently (Figure 8-40b, c).

Similar observations have been made for other *Drosophila* enhancers. In most cases, the strength of an enhancer is related primarily to how frequently transcriptional bursts are initiated. Additional research is needed to fully understand the mechanism(s) underlying transcriptional bursting and its regulation by enhancers. However, in vitro transcription experiments with yeast extracts indicate that after the first round of transcription from an added template DNA, TBP and possibly other general transcription factors (GTFs) remain associated with promoter DNA forming a partially assembled preinitiation complex (PIC) scaffold that allows very rapid assembly of the next preinitiation complex and subsequent initiation by Pol II. These observations and other in vitro transcription experiments with purified factors have led to the model that an interaction between enhancer-bound factors, Mediator, and transcription factors bound to promoter-proximal elements promotes the assembly of a Pol II preinitiation complex that initiates, leaving behind a scaffold of TBP bound to the promoter that can reassemble and initiate transcription up to 100 times before the scaffold dissociates from the promoter. This is postulated to result in the observed bursts of transcription. Strong enhancers are proposed to increase the frequency of these bursts by stimulating the rate of assembly of general transcription factors into the first PIC that initiates the transcriptional burst, while weak

enhancers are proposed to cause the assembly of PICs on the regulated promoter at a lower frequency.

KEY CONCEPTS OF SECTION 8.4

Molecular Mechanisms of Transcription Repression and Activation

- Eukaryotic transcription activators and repressors exert their effects largely by binding to multisubunit co-activators or co-repressors that influence the assembly of preinitiation complexes either by modulating chromatin structure or by interacting with Pol II and general transcription factors.
- The DNA in condensed regions of chromatin (heterochromatin) is relatively inaccessible to transcription factors and other proteins, so that gene expression in these regions is repressed.
- The interactions of several proteins with one another and with the hypoacetylated N-terminal tails of histones H3 and H4 are responsible for the chromatin-mediated repression of transcription that occurs in the telomeres and the silent mating-type loci in *S. cerevisiae* (see Figure 8-32).
- Some repression domains function by interacting with co-repressors that are histone deacetylase complexes. The subsequent deacetylation of histone N-terminal tails in nucleosomes near the repressor-binding site inhibits interaction between the promoter DNA and general transcription factors, thereby repressing transcription initiation (see Figure 8-33a).
- Activation domains function by binding multiprotein co-activator complexes such as histone acetylase complexes. The subsequent hyperacetylation of histone N-terminal tails in nucleosomes near the activator-binding site facilitates interactions between the promoter DNA and general transcription factors, thereby stimulating transcription initiation (see Figure 8-33b).
- SWI/SNF chromatin-remodeling factors constitute another type of co-activator. These multisubunit complexes can transiently dissociate DNA from histone cores in an ATP-dependent reaction and may also decondense regions of chromatin, thereby promoting the binding of DNA-binding proteins needed for transcription initiation.
- The Mediator complex, another type of co-activator, is a roughly 30-subunit complex that forms a molecular bridge between activation domains and RNA polymerase II by binding directly to the polymerase and activation domains. By binding to several

different activators either simultaneously or in rapid succession, Mediator probably helps integrate the effects of multiple activators on a single promoter (see Figure 8-37).

- Activators bound to a distant enhancer can interact with transcription factors bound to a promoter because chromatin is flexible and the intervening chromatin can form a large loop.

8.5 Regulation of Transcription-Factor Activity

We have seen in the preceding discussion how combinations of transcription factors binding to specific DNA regulatory sequences control transcription of eukaryotic genes. Consequently, the nuclear concentrations and activities of the transcription factors that interact with the transcription-control regions of a gene are crucial to determining whether a specific gene in a multicellular organism is expressed in a particular cell at a particular time during development or in differentiated cells. As we have seen, local chromatin structure also contributes to transcription regulation in eukaryotes, as in the case of Sir protein repression at telomeres and the silent mating-type loci in yeast (see Figure 8-32). In the next section, we discuss other examples of chromatin-mediated control that can result in *transcriptional memory*. Here we discuss regulation of transcription-factor expression and activity.

Which transcription factors are expressed in a particular cell type is determined by previous interactions between other transcription factors and control regions in transcription-factor genes that occur during development and differentiation of that cell type. We now have a high-resolution view of how transcription-factor binding changes during development and differentiation of multiple human cell types. This understanding is due to the identification of DNase I hypersensitive sites on a genomic scale.

DNase I Hypersensitive Sites Reflect the Developmental History of Cellular Differentiation

In Chapter 7, we learned that an expressed gene is far more sensitive to digestion by the nuclease DNase I than when the gene is not expressed (see Figure 7-27). In addition to this general increase in DNase I sensitivity over the length of a gene, researchers have found that specific short regions of the genome are extremely sensitive to DNase I digestion compared to the vast majority of the DNA in chromatin. These stretches of DNA are on the order of a hundred base pairs in length, and are the first regions cut when isolated nuclei are treated with low levels of DNase I. These cut regions are known as *DNase I hypersensitive sites (DHSs)*. High-throughput sequencing methods have allowed mapping of DHSs across the genome in multiple differentiated and embryonic cell types. Briefly, after digestion of isolated nuclei with low levels of DNase I, DNA is isolated from the treated chromatin. Oligonucleotide linkers of a known sequence are ligated to the DNA ends generated by DNase I digestion. The DNA is sheared into small fragments by sonication, amplified by PCR, and sequenced. Using this approach, human DNA sequences adjacent to the oligonucleotide linker sequence were thus identified as DHSs.

Figure 8-41a shows plots of the number of times a DHS was sequenced in samples from the human cell types indicated at the

left. The frequency at which genomic DNA within an interval of 1 kb along the length of a chromosome is observed by this method is a measure of the DNase sensitivity of this 1 kb region of the genome. The height of each vertical bar represents the degree of sensitivity of the DNA sequence at that position to digestion in nuclei isolated from each of the cell types. A roughly 600-kb region of the genome on chromosome 9 is shown.

FIGURE 8-41 Maps of DNase I hypersensitive sites in embryonic and adult cells reflect their developmental history. (a) DHSs from each of the human cell types shown at the left

are mapped in an interval on chromosome 9. The height of each vertical bar in the figure represents the number of times a sequence in a 50-bp interval at that position was sequenced and represents DNase sensitivity. The plots are color-coded according to the embryonic tissue from which they developed. (b) Dendrogram showing the relationships among the DHS maps for each cell type across the entire genome. The embryonic tissue from which each of these cell types develops is shown at the right. Embryonic stem cells form the root of the dendrogram. The DHS maps for all other cell types are derived from those for the embryonic stem cell by loss of some DHSs and the acquisition of other DHSs. The dendrogram, based on how closely DHS maps from two cell types are related, parallels the developmental relationships among the cell types.

[Republished with permission from Elsevier, from A. B. Stergachis et al., 2013, "Developmental Fate and Cellular Maturity Encoded in Human Regulatory DNA Landscapes," *Cell*, **154**:888–903; permission conveyed through Copyright Clearance Center, Inc.]

DHSs appear to be sites where sequence-specific binding proteins, such as transcription factors, bind to DNA. Consequently, the DHS pattern in a region of chromatin indicates the positions of bound transcription factors, although the transcription factors bound are not directly identified.

In Figure 8-41a, the type of tissue from which the DHS data were determined is shown on the left, and the embryonic tissues from which these tissue types developed are color-coded as indicated in Figure 8-41b. It is apparent that more closely related cell types, such as fibroblasts from different regions of the body, or endothelial cells that line the inner surfaces of blood vessels from different organs, have more similar DHSs than more distantly related cell types. With computer methods, it is possible to compare the similarity of the DHS maps for each of these cell types across the entire genome.

With these computational methods, a dendrogram can be generated showing how closely the DHS map from one cell type resembles those of other cell types (see Figure 8-41b). This dendrogram is similar to the dendrograms used to show the relatedness, and hence the evolution, of gene sequences (see Figure 6-24b).

Importantly, the DHS pattern of embryonic stem cells is at the root of the DHS dendrogram for all cell types (see Figure 8-41b). These cells from the inner cell mass of the early mammalian embryo (discussed in Chapter 22; see Figure 22-4) are the progenitors of all cells in the adult organism. Embryonic stem cells have the largest number of DHSs, suggesting that they have the most complex transcriptional control of all cells: about 257,000 DHSs in one study, compared with 90,000–150,000 in differentiated cells. This difference probably reflects the developmental potential of embryonic stem cells. Approximately 50,000–100,000 DHSs that are not found in embryonic stem cells arise during development. Note that for each adult cell type, a different set of new DHSs arises. These DHS patterns reveal the complexity of the combinations of transcription factors that regulate each gene.

Approximately a million distinct DHSs were characterized in the cell types shown in Figure 8-41. Since DHSs include clustered transcription-factor binding sites typical of enhancers, these results suggest that on average, combinations of four or five enhancers regulate the transcription of each of the roughly 19,000 genes in the human genome. The maps of DHSs reveal where binding of early

embryonic transcription factors is lost and where new cell-type-specific combinations of transcription factors bind as a cell differentiates. Even this estimate fails to capture the complexity of transcriptional control, since many transcription-factor-binding sites detected as one DHS are, in fact, bound by related transcription factors with similar DNA-binding domains in different cell types. The related transcription factors regulate the appropriate level of transcription for that cell type.

Nuclear Receptors Are Regulated by Lipid-Soluble Hormones

In addition to controlling the expression of transcription factors, cells also regulate the activity of many of their transcription factors once they have been expressed. For example, the activity of many transcription factors is regulated by signals received from other cells. Interactions between extracellular domains of transmembrane-receptor proteins on the surface of the cell and specific protein ligands for these receptors secreted by other cells, or expressed on the surface of neighboring cells, activate intracellular domains of the transmembrane proteins. The result is that the signal received on the outside of the cell is transduced to a signal on the inside of the cell. The intracellular signal regulates the activities of enzymes that modify transcription factors by post-translational protein modifications, such as phosphorylation,

acetylation, and proteosomal degradation (see Figure 3-32). These post-translational modifications activate or inhibit transcription factors in the nucleus. In Chapters 15 and 16, we describe the major types of cell-surface receptors, the protein ligands they bind, and the intracellular signaling pathways that regulate transcription-factor activity.

Here we discuss a group of extracellular signals that use a (somewhat) different pathway to regulate the activities of transcription factors: small, lipid-soluble hormones, including steroid hormones, retinoids, and thyroid hormones. These lipid-soluble hormones diffuse through the plasma and nuclear membranes and interact directly with the transcription factors they control (Figure 8-42). One group of transcription factors that we mentioned already, the *nuclear-receptor superfamily*, needs to bind to lipid-soluble hormones to convert the transcription factors into transcriptional activators. We will now consider these interactions in more detail.

FIGURE 8-42 Examples of hormones that bind to nuclear receptors. These and related lipid-soluble hormones diffuse through the plasma and nuclear membranes and bind to receptors located in the cytosol or nucleus. The ligand-receptor complex functions as a transcription activator.

All Nuclear Receptors Share a Common Domain Structure

cDNA sequencing of mRNAs encoding various nuclear receptors has revealed a remarkable conservation in their amino acid sequences. It has also revealed that each of these receptors has three functional regions (Figure 8-43). The first is a unique N-terminal region of variable length (100–500 amino acids). Portions of this variable region function as activation domains in most nuclear receptors. The second is a DNA-binding domain that maps near the center of the primary sequence and contains a repeat of the C_4 zinc-finger motif (see Figure 8-25b). The third region, the hormone-binding domain, located near the C-terminal end, contains a hormone-dependent activation domain (see Figure 8-26b, c). In some nuclear receptors, the hormone-binding domain functions as a repression domain in the absence of ligand.

FIGURE 8-43 General design of transcription factors in the nuclear-receptor superfamily. The centrally located DNA-binding domain exhibits considerable sequence homology among different receptors and contains two copies of the C_4 zinc-finger motif (see Figure 8-25b). The C-terminal hormone-binding domain exhibits somewhat less homology. The N-terminal regions of various receptors vary in length, have unique sequences, and may contain one or more activation domains. See R. M. Evans, 1988, *Science* **240**:889.

Nuclear-Receptor Response Elements Contain Inverted or Direct Repeats

The DNA sites to which nuclear receptors bind are called *response elements*. The nucleotide sequences of several response elements have been determined. The consensus sequences of response elements for two steroid hormone receptors, the glucocorticoid receptor response element (GRE) and the estrogen receptor response element (ERE) are 6-bp inverted repeats separated by any three base pairs (Figure 8-44a, b). This finding suggested that the cognate steroid hormone receptors would bind to DNA as symmetric

dimers. This was confirmed by x-ray crystallographic analysis of the homodimeric glucocorticoid receptor's C_4 zinc-finger DNA-binding domain (see Figure 8-25b).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

FIGURE 8-44 Consensus sequences of DNA response elements that bind five nuclear receptors. (a, b) The glucocorticoid and estrogen receptors are twofold symmetric dimers that bind, respectively, to the glucocorticoid receptor response element (GRE) and the estrogen receptor response element (ERE). Each of these response elements contains inverted repeats separated by three base pairs. (c–e) The heterodimeric nuclear receptors each contain one RXR subunit associated with another nuclear-receptor subunit that defines the hormone response. RXR-VDR mediates responses to vitamin D_3 by binding to a direct repeat separated by three base pairs (a VDRE). RXR-TR mediates responses to thyroid hormone by binding to the same DNA bases in a direct repeat separated by four base pairs (a TRE). Similarly, RXR-RAR mediates a response to retinoic acid by binding to the same direct repeat separated by five base pairs, comprising a RARE. The repeat sequences bound by the reading helices of these receptors are indicated by red arrows. (f) Crystal structures of the glucocorticoid receptor bound to DNA containing a GRE (*top*) and of the RXR-TR heterodimer bound to DNA containing a TRE (*bottom*). Red arrows indicate the orientation from N to C of the reading helices. Note that in the twofold symmetric glucocorticoid receptor, the reading helices are inverted relative to each other so that they "read" an AGAACA on the top strand of the left half-site and on the bottom strand of the right half-site, separated by 3 base pairs. Consequently, the binding site for the glucocorticoid receptor and other twofold symmetric homodimers such as the estrogen receptor is an inverted repeat [see (a) and (b)]. In contrast, the reading helices in the RXR-TR heterodimer are in the same orientation. Consequently, they read an AGGTCA sequence in the same orientation in the two-half sites separated by four base pairs, a direct-repeat binding site. The interface between the RXR subunit and the vitamin D_3 receptor (VDR) subunit bound to a VDRE brings the two reading helices closer together so that they bind to the same half-sites separated by three rather than four base pairs. Similarly, the interface between the RXR and RAR subunits bound to a RARE positions the two reading helices in the heterodimer farther apart than in the RXR-TR, so that they bind the same AGGTCA sequences

separated by five base pairs. See K. Umesono et al., 1991, *Cell* **65**:1255, and A. M. Naar et al., 1991, *Cell* **65**:1267.

[Part (f) Data from F. Rastinejad et al., 1995, *Nature* **375**:203.]

Some nuclear-receptor response elements, such as those for the receptors that bind nonsteroids such as vitamin D_3, thyroid hormone, and retinoic acid, are direct repeats of the same sequence that is recognized by the estrogen receptor, separated by three, four, or five base pairs (Figure 8-44c–e). The specificity of these response elements is determined by the spacing between the repeats. The nuclear receptors that bind to these direct-repeat response elements do so as heterodimers, all of which share a monomer called *RXR*. The vitamin D_3 response element (VDRE), for example, is bound by the RXR-VDR heterodimer, and the retinoic acid response element (RARE) is bound by RXR-RAR. The monomers composing these heterodimers interact with each other in such a way that the two DNA-binding domains lie in the same orientation, allowing the RXR heterodimers to bind to direct repeats of the binding site for each monomer (Figure 8-44f). In contrast, the monomers in homodimeric nuclear receptors (e.g., GRE and ERE) have an inverted orientation.

Hormone Binding to a Nuclear Receptor Regulates Its Activity as a Transcription Factor

The mechanism by which hormone binding controls the activity of nuclear receptors differs between heterodimeric and homodimeric receptors. Heterodimeric nuclear receptors (e.g., RXR-VDR, RXR-TR, and RXR-RAR) are located in the nucleus. In the absence of their hormone ligand, they repress transcription when bound to their cognate sites in DNA. They do so by directing histone deacetylation at nearby nucleosomes by associating with histone deacetylase complexes, as described earlier for other repressors (see Figure 8-33a). When a heterodimeric nuclear receptor binds its ligand, the receptor undergoes a conformational change, and as a consequence, it dissociates from histone deacetylase complexes and binds histone acetylase complexes, thereby reversing its own repressing effects. In the presence of ligand, the ligand-bound conformation of the receptor also binds Mediator, stimulating preinitiation complex assembly.

In contrast to heterodimeric nuclear receptors, homodimeric receptors are found in the cytoplasm in the absence of their hormone ligands. When a hormone binds to its receptor, the hormone-receptor complex translocates into the nucleus. The hormone-dependent translocation of the homodimeric glucocorticoid receptor (GR) was demonstrated in the experiments shown in Figure 8-45a–c. The GR hormone-binding domain alone mediates this transport. Subsequent studies showed that in the absence of hormone, GR cannot be transported into the nucleus because its ligand-binding domain is partially unfolded and associates reversibly with Hsp70, a major cellular protein chaperone

that assists folding of nascent polypeptides in the cytoplasm (see Figure 3-19a). As long as the receptor is confined to the cytoplasm, it cannot interact with target genes and hence cannot activate transcription. Hormone binding promotes an exchange of GR from Hsp70 to Hsp90 (see Figure 3-19b), which, with coupled hydrolysis of ATP, refolds the GR ligand-binding domain, increasing the affinity for hormone and releasing GR from Hsp70 so that it can enter the nucleus. Once in the nucleus in the conformation induced by ligand binding, the GR can bind to response elements associated with target genes (Figure 8-45d). Once the receptor with bound hormone binds to a response element, it activates transcription by interacting with chromatin-remodeling and histone acetylase complexes and Mediator.

EXPERIMENTAL FIGURE 8-45 Fusion proteins from expression vectors demonstrate that the hormone-binding domain of the glucocorticoid receptor mediates translocation to the nucleus in the presence of hormone. Cultured animal cells were transfected with expression vectors encoding the proteins diagrammed in part (d). Immunofluorescence with a labeled antibody specific for β-galactosidase was used to detect the expressed proteins in transfected cells. (a) In cells that expressed β-galactosidase alone, the enzyme was localized to the cytoplasm in the presence and absence of the glucocorticoid hormone dexamethasone (Dex). (b) In cells that expressed a fusion protein consisting of β-galactosidase and the entire glucocorticoid receptor (GR), the fusion protein was present in the cytoplasm in the absence of hormone but was transported to the nucleus in the presence of hormone. (c) Cells that expressed a fusion protein composed of β-galactosidase and only the

GR ligand-binding domain (light purple) also exhibited hormone-dependent transport of the fusion protein to the nucleus. (d) Model of hormone-dependent gene activation by a homodimeric nuclear receptor. In the absence of hormone, the receptor is kept in the cytoplasm by interaction between its ligand-binding domain (LBD) and chaperone proteins. When hormone is present, it diffuses through the plasma membrane and binds to the ligand-binding domain, causing a conformational change that releases the receptor from the chaperone proteins. The receptor with bound ligand is then translocated into the nucleus, where its DNA-binding domain (DBD) binds to response elements, allowing the ligand-binding domain and an additional activation domain (AD) at the N-terminus to stimulate transcription of target genes.

Metazoans Regulate the RNA Polymerase II Transition from Initiation to Elongation

A recent unexpected discovery that resulted from application of the chromatin immunoprecipitation technique is that a large fraction of genes in metazoans have a paused elongating RNA polymerase II within about 50–100 bp of the transcription start site. Thus expression of the encoded protein is controlled not only by transcription initiation but also by transcription elongation early in the transcription unit. The first genes discovered to be regulated by

control of transcription elongation were **heat-shock genes** (e.g., *hsp70*), which encode molecular chaperones that refold denatured proteins and other proteins that help the cell deal with the effects of heat shock. When heat shock occurs, the heat-shock transcription factor (HSF1) is activated (see Chapter 21). Binding of activated HSF1 to specific sites in the promoter-proximal region of heat-shock genes stimulates the paused polymerase to continue chain elongation and promotes rapid reinitiation by additional Pol II molecules, leading to many transcription initiations per minute. This mechanism of transcriptional control permits a rapid response: these genes are always paused in a state of suspended transcription and therefore, when an emergency arises, no time is required to remodel and acetylate chromatin at the promoter and assemble a transcription preinitiation complex.

Another transcription factor known to regulate transcription elongation is MYC, which functions in the regulation of cell growth and division. MYC is often expressed at high levels in cancer cells and is a key transcription factor in the reprogramming of somatic cells into pluripotent stem cells capable of differentiation into any cell type. The ability to induce differentiated cells to convert to pluripotent stem cells has elicited enormous research interest because of its potential for the development of therapeutic treatments for traumatic injuries to the nervous system and degenerative diseases (see Chapter 22).

Termination of Transcription Is Also Regulated

Once Pol II has transcribed about 50 nucleotides from the transcription start site, elongation through most genes is highly processive. Chromatin immunoprecipitation with antibody to Pol II, however, indicates that the amount of Pol II at various positions in a transcription unit in a population of cells varies greatly (see Figure 8-12b, *right*). This finding indicates that the enzyme can elongate through some regions much more rapidly than others. In most cases, Pol II does not terminate transcription until after a sequence is transcribed that directs cleavage and polyadenylation of the RNA at the 3′ end of the encoded mRNA. Pol II can then terminate transcription at multiple sites located 0.5–2 kb beyond this poly(A) addition site. Experiments with mutant genes show that termination is coupled to the process that cleaves and polyadenylates the 3′ end of a transcript, which is discussed in the next chapter.

KEY CONCEPTS OF SECTION 8.5

Regulation of Transcription-Factor Activity

- The activities of many transcription factors are indirectly regulated by binding of extracellular proteins and peptides to cell-surface receptors. These receptors activate intracellular signal transduction pathways that regulate specific transcription factors through a variety of mechanisms discussed in Chapter 16.
- Nuclear receptors constitute a superfamily of dimeric C_4 zinc-finger transcription factors that bind lipid-soluble hormones and interact with specific response elements in DNA (see Figures 8-41 and 8-43).

- Hormone binding to nuclear receptors induces conformational changes that modify the interactions of these receptors with other proteins (see Figure 8-26b, c).
- Heterodimeric nuclear receptors (e.g., those for retinoids, vitamin D, and thyroid hormone) are found only in the nucleus. In the absence of hormone, they repress transcription of target genes with the corresponding response element. When bound to their ligands, they activate transcription.
- Steroid hormone receptors are homodimeric nuclear receptors. In the absence of hormone, they are trapped in the cytoplasm by molecular chaperones. When bound to their ligands, they can translocate to the nucleus and activate transcription of target genes (see Figure 8-44).
- In metazoans, RNA polymerase II often pauses during elongation within approximately 50–100 base pairs from the transcription start site. Release from this pause contributes to the regulation of gene transcription.
- Termination by RNA polymerase II is coupled to cleavage of transcripts at the end of the final exon followed by polyadenylation. Cleavage and polyadenylation are considered further in Chapter 9.

8.6 Epigenetic Regulation of Transcription

The term **epigenetics** refers to the study of inherited changes in the phenotype of a cell that do not result from changes in DNA sequence. For example, during the differentiation of bone marrow stem cells into the several different types of blood cells, a hematopoietic stem cell divides into two daughter cells, one of which continues to have the properties of a hematopoietic stem cell, including the potential to differentiate into all the different types of blood cells. But the other daughter cell becomes a type of progenitor cell that normally can differentiate into lymphocytes or myeloid cells (see **Figure 22-18**). Lymphoid progenitor cells generate daughter cells that differentiate into lymphocytes, which perform many of the functions involved in immune responses to pathogens (see Chapter 24). Myeloid progenitor cells divide into daughter cells that are committed to differentiating into red blood cells, different kinds of phagocytic white blood cells, or the cells that generate platelets involved in blood clotting. Lymphoid and myeloid progenitor cells both have the same DNA sequence as the zygote (generated by fertilization of an egg cell by a sperm cell) from which they developed, but they have restricted developmental potential because of epigenetic differences between them.

Such epigenetic changes are initially the consequence of the expression of specific master-transcription factors that are

regulators of cellular differentiation, controlling the expression of other genes that encode transcription factors and proteins involved in cell-cell communication in complex networks of gene control. Understanding these networks is currently the subject of intense investigation. Changes in gene expression initiated by transcription factors are often reinforced and maintained over multiple cell divisions by post-translational modifications of histones and methylation of DNA at position 5 of the cytosine pyrimidine ring (see Figure 2-17). These changes to chromatin are maintained and propagated to daughter cells when cells divide. Consequently, the term *epigenetic marks* is used to refer to such post-translational modifications of histones and 5-methyl C modification of DNA.

DNA Methylation Regulates Transcription

Recall that most promoters in mammals fall into the CpG island class. Active CpG island promoters have unmethylated cytosines in their CG sequences. Unmethylated CpG island promoters have reduced affinity for histone octamers. But nucleosomes immediately neighboring the unmethylated promoters are methylated at histone H3 lysine 4. These methylated nucleosomes are associated with Pol II molecules that have paused during transcription of both the sense and antisense template-DNA strands (see Figures 8-12 and 8-13). Recent research indicates that methylation of histone H3 lysine 4

occurs in mouse cells because a protein named Cfp1 (CXXC finger protein 1) binds unmethylated CpG-rich DNA through a zinc-finger domain (CXXC) and associates with a histone methylase (Setd1) specific for histone H3 lysine 4. Chromatin-remodeling complexes and the general transcription factor TFIID, which initiates Pol II preinitiation complex assembly (see Figure 8-13), associate with nucleosomes bearing the H3 lysine 4 trimethyl mark, thus promoting Pol II transcription initiation.

In differentiated cells, a small percentage of specific CpG island promoters, depending on the cell type, have CpGs marked by 5-methyl C. A family of proteins binds to DNA that is rich in 5-methyl C–modified CpGs. Once bound, these methyl CpG-binding proteins, or MBDs, associate with histone deacetylases and repressive chromatin-remodeling complexes that condense chromatin, resulting in transcriptional repression. The 5-methyl C is added to the CpGs by DNA methyl transferases named DNMT3a and DNMT3b. They are referred to as *de novo DNA methyl transferases* because they methylate Cs in a region where there is no 5-methyl C in either DNA strand. Much remains to be learned about how DNMT3a and b are directed to specific CpG islands. But once they have methylated a DNA sequence, methylation at that C is passed on through DNA replication through the action of the ubiquitous *maintenance* methyl transferase DNMT1 (red indicates daughter strands):

As a consequence, once a CpG island promoter is methylated by DNMT3a or b, it continues to be methylated by DNMT1 in subsequent daughter cells. Consequently, the promoter remains repressed in all subsequent daughter cells through interactions with MBDs, even after the stimulus for the initial C-methylation by DNMT3a or b has ceased. Therefore, repression of C-methylated promoters is inherited through cell division. This mechanism of epigenetic repression is being intensely investigated because tumor-suppressor genes encoding proteins that function to suppress the development of cancer are often inactivated in cancer cells by abnormal CpG methylation of their promoter regions. This is discussed further in Chapter 25.

Methylation of Specific Histone Lysines Is Linked to Epigenetic Mechanisms of Gene Repression

Figure 7-26b summarized the major different types of post-translational modifications that are found on histones, including acetylation and methylation of lysines. The acetylation state at a specific histone lysine on a particular nucleosome results from a dynamic equilibrium between acetylation and deacetylation by

histone acetylases and histone deacetylases. Acetylation of histones in a localized region of chromatin predominates when local DNA-bound activators transiently bind histone acetylase complexes. Deacetylation predominates when repressors transiently bind histone deacetylase complexes. Pulse-chase radiolabeling experiments have shown that acetyl groups on histone lysines turn over rapidly through the sequential actions of these competing enzymes.

In contrast, methyl groups on histones are much more stable. Methylation of lysine occurs on the nitrogen atom of the terminal ε-amino group of the lysine side chain (see Figure 2-14). Lysines can be modified by the addition of one, two, or three methyl groups to this terminal nitrogen atom, generating mono-, di-, and trimethylated lysine, all of which carry a single positive charge. Histone lysine methyl groups can be removed by *histone lysine demethylases.* But the resulting turnover of histone lysine methyl groups is much slower than the turnover of histone lysine acetyl groups, which makes methylation a more appropriate post-translational modification for propagating epigenetic information.

Three other common post-translational modifications of histones have been characterized (see Figure 7-26b). Through study of these histone modifications and their effects on transcription and other processes like the formation of mitotic chromosomes, a picture of chromatin has emerged. We know that the histone tails extending as

random coils from the chromatin fiber are modified to generate one of many possible combinations of modifications that regulate chromatin-based processes by affecting the binding of a large number of different protein complexes. This control of protein interactions with specific regions of chromatin that results from the combined influence of post-translational modifications of histones has been called a *histone code.* Some of these modifications, such as histone lysine acetylation, are rapidly reversible, whereas others, such as histone lysine methylation, can be epigenetically inherited. Table 8-2 summarizes the post-translational modifications that make up the histone code.

TABLE 8-2 • Histone Post-Translational Modifications Associated with Active and Repressed Genes

Modification	Sites of Modification	Effect on Transcription
Acetylated lysine	H3 (K9, K14, K18, K23, K27)	Activation
	H4 (K5, K8, K12, K16)	Activation
	H2A (K5, K8, K13)	Activation
	H2B (K5, K12, K15, K20)	Activation
Hypoacetylated lysine		Repression
Phosphorylated serine/threonine	H3 (T3, S10, T11, S28)	Activation
	H2A (S1, T120)	Activation

	H2B (S14)	Activation
Methylated arginine	H3 (R2, R17, R26)	Activation
	H4 (R3)	Activation
Methylated lysine	H3 (K4) Me3 in promoter region	Activation
	H3 (K4) Me1 in enhancers	Activation
	H3 (K36, K79) in transcribed region	Elongation
	H3 (K9, K27) Me2/3	Repression
	H4 (K20) Me2/3	Repression
Ubiquitinylated lysine	H2B (K120 in mammals, K123 in *S. cerevisiae*)	Activation
	H2A (K119 in mammals)	Repression

Histone H3 Lysine 9 Methylation in Heterochromatin

In most eukaryotes, some co-repressor complexes contain histone methyl transferase subunits that methylate histone H3 at lysine 9, generating di- and trimethyl lysines. These methylated lysines are binding sites for isoforms of HP1 protein, which functions in the condensation of heterochromatin, as discussed in Chapter 7 (see Figure 7-28). For example, the KAP1 co-repressor complex functions with a class of more than 200 zinc-finger–transcriptional repressors

encoded in the human genome. The co-repressor complex includes a subunit with H3 lysine 9 methyl transferase activity that methylates nucleosomes over the promoter regions of genes targeted for repression by these zinc-finger repressors. This results in HP1 binding to these promoter regions, chromatin condensation, and transcriptional repression. An integrated transgene in cultured mouse fibroblasts that was repressed through the action of the KAP1 co-repressor was associated with heterochromatin in most cells, whereas the active form of the same transgene was associated with euchromatin (Figure 8-46). Chromatin immunoprecipitation assays showed that the repressed gene was associated with histone H3 methylated at lysine 9 and with HP1, whereas the active gene was not.

EXPERIMENTAL FIGURE 8-46 Association of a repressed transgene with heterochromatin. Mouse fibroblasts were stably transformed with a transgene that contained binding sites for an engineered repressor. The repressor was a fusion between a DNA-binding domain, a repression domain that interacts with

the KAP1 co-repressor complex, and the ligand-binding domain of a nuclear receptor that allows the nuclear import of the fusion protein to be controlled experimentally (see Figure 8-45). DNA was stained blue with the dye DAPI. Brighter-staining regions are regions of heterochromatin, where the DNA concentration is higher than in euchromatin. The transgene was detected by hybridization of a fluorescently labeled complementary probe (green). When the recombinant repressor was retained in the cytoplasm, the transgene was transcribed (*left*) and was associated with euchromatin in most cells. When hormone was added so that the recombinant repressor entered the nucleus, the transgene was repressed (*right*) and associated with heterochromatin. Chromatin immunoprecipitation assays (see Figure 8-12) showed that the repressed gene was associated with histone H3 methylated at lysine 9 and HP1, whereas the active gene was not.

[Republished with permission from Cold Spring Harbor Laboratory Press, from K. Ayyanathan et al., 2003, "Regulated Recruitment of HP1 to a Euchromatic Gene Induces Mitotically Heritable, Epigenetic Gene Silencing: A Mammalian Cell Culture Model of Gene Variegation," *Genes Dev.*, **17**:1855–1869; Fig. 6.]

Importantly, H3 lysine 9 methylation is maintained following chromosome replication by the mechanism diagrammed in Figure 8-47. When a methylated region of DNA is replicated in S phase, the nucleosomes associated with the parent DNA are randomly distributed to the daughter DNA molecules. New histone octamers that are not methylated on H3 lysine 9 also associate randomly with the new daughter chromosomes to reestablish the density of nucleosomes before DNA replication, but since the parent nucleosomes are associated with both daughter chromosomes, approximately half of the daughter chromosomes' nucleosomes are methylated on lysine 9. The repressor complex also contains a subunit with a *chromo* domain that binds histone H3 trimethylated at

lysine 9 (H3K9me3). This causes the co-repressor complex to associate with the newly replicated chromatin in which about half the nucleosomes contain H3K9me3. As a result, the methylase subunit of the co-repressor complex is brought into sufficiently close proximity to the H3 histone N-terminal tails of the newly assembled histone octamers that they methylate all the H3 N-termini associated with that region of chromatin, leading to HP1 association and chromatin condensation (see Figure 7-28). Repetition of this process with each cell division results in maintenance of H3 lysine 9 methylation of this region of the chromosome.

FIGURE 8-47 Maintenance of histone H3 lysine 9 methylation during chromosome replication. When chromosomal DNA is replicated, the parent histones randomly associate with the two daughter chromosomes, while unmethylated histones synthesized during S phase are assembled into other nucleosomes in those same daughter chromosomes. Association of histone H3 lysine 9 methyl transferases (H3K9 HMT) with parent nucleosomes bearing the histone 3 lysine 9 di- or trimethylation mark methylates the newly added unmodified nucleosomes. Consequently, histone H3 lysine 9 methylation marks are maintained during repeated cell divisions unless they are specifically removed by a histone demethylase.

Epigenetic Control by Polycomb and Trithorax Complexes

A critical type of epigenetic mark found in multicellular animals and plants involves a set of proteins known collectively as *Polycomb* and a counteracting set of proteins known as *Trithorax*. These names were derived from the phenotypes of mutations in the genes encoding these proteins in *Drosophila*, in which they were first discovered. Polycomb is essential for maintaining the repression of genes in specific types of cells, and in all of the cells that descend from them, throughout the life of an organism. Important genes that are repressed by Polycomb proteins include the Hox genes, which encode master regulatory transcription factors. Different combinations of Hox transcription factors help to direct the development of specific tissues and organs in a developing embryo. Early in embryogenesis, expression of Hox genes is controlled by

typical activator and repressor proteins. However, the expression of these activators and repressors stops at an early point in embryogenesis. Correct expression of Hox genes in the descendants of early embryonic cells is maintained for the remainder of embryogenesis and into adult life by Polycomb and Trithorax proteins. Polycomb proteins maintain the *repression* of specific Hox genes in all cells that descend from early embryonic cells where the Hox gene was repressed in the early embryo. Trithorax proteins perform the opposite function; they maintain the *expression* of Hox genes in the descendants of early embryonic cells that expressed the Hox gene. Polycomb and Trithorax proteins control thousands of genes, including genes that regulate cell growth and division. Polycomb and Trithorax genes are often mutated in cancer cells, contributing to the abnormal properties of these cells (see Chapter 25).

Remarkably, virtually all cells in the developing embryo and adult express a similar set of Polycomb and Trithorax proteins, and all cells contain the same set of Hox genes. Yet only the Hox genes in descendants of cells where they were initially repressed in early embryogenesis remain repressed, even though the same Hox genes in other cells in a neighboring region of the embryo remain active in the presence of the same Polycomb proteins. Consequently, as in the case of the yeast silent mating-type loci (see Section 8.4), the expression of Hox genes is regulated by a process that involves more

than specific DNA sequences interacting with proteins that diffuse through the nucleoplasm.

A current model for repression by Polycomb proteins is depicted in Figure 8-48. Most Polycomb proteins are subunits of one of two classes of multiprotein *P*olycomb *r*epressive *c*omplexes: PRC1 and PRC2. The PRC2 complexes are thought to act initially by associating with the repression domains of specific repressors bound to their cognate DNA sequences early in embryogenesis, or with ribonucleoprotein complexes containing long noncoding RNAs, which will be discussed in the next section. The PRC2 complexes contain histone deacetylases that inhibit transcription. They also contain a subunit [E(z) in *Drosophila*, EZH2 in mammals] with a *SET domain*, which is the catalytic domain of several histone methyl transferases. The SET domain in PRC2 methylates histone H3 on lysine 27, generating di- and trimethyl lysines (H3K27me2 and H3K27me3). A PRC1 complex then binds the nucleosomes with H3K27me2 and 3 through dimeric Pc subunits (CBXs in mammals), each containing a methyl lysine–binding chromodomain specific for methylated H3 lysine 27. It has been proposed that binding of the dimeric Pc to neighboring nucleosomes condenses the chromatin into a structure that inhibits transcription. This proposal is supported by electron microscopy studies showing that PRC1 complexes cause nucleosomes to associate in vitro (see Figure 8-48d, e).

FIGURE 8-48 Model for repression by Polycomb complexes. (a) During early embryogenesis, repressors associate with the PRC2 complex. (b) This association results in methylation (Me) of neighboring nucleosomes on histone H3 lysine 27 (K27) by the SET domain–containing subunit E(z). (c) The PRC1 complex binds nucleosomes methylated at H3 lysine 27 through a dimeric, chromodomain-containing subunit Pc. The PRC1 complex condenses the chromatin into a repressed chromatin structure. PRC2 complexes associate with PRC1 complexes to maintain H3 lysine 27 methylation of neighboring histones. As a consequence, PRC1 and PRC2 association with the region is maintained when expression of the repressor proteins in (a) ceases. (d, e) Electron micrograph of a 1-kb fragment of DNA bound by four nucleosomes in the absence (d) and presence (e) of one PRC1 complex per five nucleosomes. See A. H. Lund and M. van Lohuizen, 2004, *Curr. Opin. Cell Biol.* **16**:239; and N. J. Francis, R. E. Kingston, and C. L. Woodcock, 2004, *Science* **306**:1574.

[Part (d)–(e) Republished with permission from AAAS, from N. J. Francis et al., 2004, "Chromatin Compaction by a Polycomb Group Protein Complex, " *Science* **306**(5701):1574–1577; permission conveyed through Copyright Clearance Center, Inc.]

PRC1 complexes also repress transcription through additional mechanisms. The PRC1 complex contains a ubiquitin ligase that *mono*ubiquitinylates histone H2A at lysine 119 in the H2A C-terminal

tail (see Figure 7-26b). This modification of H2A blocks elongation by inhibiting a histone chaperone that removes histone octamers from DNA as Pol II transcribes through a nucleosome and then replaces them as the polymerase passes. PRC1 also associates with a histone demethylase that specifically removes methyl groups from lysine 4 of histone H3, an activating mark discussed below with Trithorax proteins.

PRC2 complexes associate with nucleosomes bearing the histone H3K27me3 mark, maintaining methylation of H3 lysine 27 in nucleosomes in the region. This methylation results in association of chromatin with PRC1 and PRC2 complexes even after expression of the initial repressor proteins shown in Figure 8-48a, b has ceased. This association maintains H3 lysine 27 methylation by a mechanism analogous to that diagrammed in Figure 8-47. This mechanism is a key feature of Polycomb repression, which is maintained through successive cell divisions for the life of an organism (∼100 years for some vertebrates and 5000 years for a bristle cone pine!).

Trithorax proteins counteract the repression mechanism of Polycomb proteins, as shown in studies of expression of the Hox transcription factor Abd-B in the *Drosophila* embryo (Figure 8-49). Abd-B is normally expressed only in posterior segments of the developing embryo. When the Polycomb system is defective, Abd-B is expressed in all cells of the embryo. When the Trithorax system is

defective and cannot counteract repression by the Polycomb system, Abd-B is repressed in most cells, except those in the very posterior of the embryo. Trithorax complexes include a histone methyl transferase that trimethylates histone H3 lysine 4, a histone methylation that is associated with the promoters of actively transcribed genes. This histone modification creates a binding site for histone acetylase and for chromatin-remodeling complexes that promote transcription, as well as for TFIID, the general transcription factor that initiates preinitiation-complex assembly (see Figure 8-13). Nucleosomes with H3 lysine 4 methylation are also binding sites for specific histone demethylases that remove H3 histone lysine 9 and lysine 27 methylation, preventing the binding of HP1 and the Polycomb repressive complexes. Nucleosomes marked with H3 lysine 4 methylation are also thought to be distributed to both daughter DNA molecules during DNA replication, resulting in maintenance of this epigenetic mark by a strategy similar to that diagrammed in Figure 8-47.

FIGURE 8-49 Opposing influence of Polycomb and Trithorax complexes on expression of the Hox transcription factor Abd-B in *Drosophila* embryos. At the stage of *Drosophila* embryogenesis shown, Abd-B is normally expressed only in posterior segments of the developing embryo, as shown at the top (*wt*) by immunostaining with a specific anti–Abd-B antibody. In embryos with homozygous mutations of *Scm*, a Polycomb gene (PcG) encoding a protein associated with the PRC1 complex, Abd-B expression is derepressed in all embryo segments. In contrast, in homozygous mutants of *trx*, a Trithorax gene (trxG), Abd-B repression is increased

so that the protein is expressed at high concentrations only in the most posterior segment.

Long Noncoding RNAs Direct Epigenetic Repression in Metazoans

Complexes have been discovered that are composed of multiple proteins that function to repress transcription bound to long RNAs. These RNAs, which can be many kilobases in length, lack long open reading frames and are consequently called **long noncoding RNAs** or **lncRNAs**. In some cases, these lncRNA-protein complexes repress genes on the same chromosome from which the RNA is transcribed, as in the case of X-chromosome inactivation in female mammals. In other cases, these RNA-protein complexes act in trans, repressing genes on chromosomes other than those from which the lncRNA is transcribed.

X-Chromosome Inactivation in Mammals

X-chromosome inactivation in female mammals (see Chapter 7) is one of the most intensely studied examples of epigenetic repression mediated by a lncRNA. X inactivation is controlled by an ∼100-kb

domain on the X chromosome called the *X-inactivation center*. Remarkably, this region encodes several lncRNAs required for the random inactivation of one entire X chromosome early in the development of female mammals. The functions of these lncRNAs are only partially understood. Some are transcribed from complementary DNA strands near the middle of the X-inactivation center: the 40-kb Tsix lncRNA and the *Xist* RNA. The latter is spliced and polyadenylated into an RNA of about 17 kb that remains in the nucleus (Figure 8-50a).

Lodish et al., *Molecular Cell Biology*, 9e, © 2021 W. H. Freeman and Company

EXPERIMENTAL FIGURE 8-50 The *Xist* long noncoding RNA encoded in the X-inactivation center coats the inactive X chromosome in cells of mammalian females, repressing transcription of most genes on the inactive X. (a) The region of the human X-inactivation center encoding the noncoding RNAs *Xist* (transcribed from the inactive X), and Tsix (transcribed from the active X). Numbers are bp from the left end of the X-chromosome. (b) A cultured fibroblast from a human female was analyzed by in situ hybridization with a probe complementary to *Xist* RNA labeled with a red fluorescent dye (*left*), a chromosome paint set of probes for the X chromosome labeled with a green fluorescent dye (*center*), and an overlay of the two fluorescent micrographs. The condensed inactive X chromosome is associated with *Xist* RNA. (c) Model for the spreading of the *Xist* lncRNA-protein complex on the inactive X chromosome during early differentiation of female embryonic stem cells. See E. Heard and A.-V. Gendrel, 2014, *Annu. Rev. Cell Dev. Biol.* **30**:561. (d) Proteins associated with *Xist* lncRNA. Question marks indicate that it is not yet known how PRC2 complexes (yellow) associate with HDAC3 and the RNA-binding protein SHARP although this might be due to formation of transcriptional condensates. See C. A. McHugh et al., 2015, *Nature* **521**:232.

[Part (b) C. M. Clemson et al., 1996, *J. Cell Biol.* **132**(3):259–275. https://doi.org/10.1083/jcb.132.3.259.]

In differentiated female cells, the inactive X chromosome is associated with 50–100 multimolecular *Xist* RNA-protein complexes dispersed along most of the length of the X-chromosome (Figure 8-50b, c). Proteins associated with these complexes include co-repressors and their associated histone deacetylase complexes, repressive chromatin remodeling complexes and polycomb complexes discussed earlier (Figure 8-48). These proteins are thought to associate through multiple weak interactions between their intrinsically disordered regions forming a repressive transcriptional condensate by the same principles discussed earlier for the formation of activating transcriptional condensates (see Figure 8-48). These repressive transcriptional condensates scattered along the X-chromosome are thought to condense the inactive X-chromosome into a chromatin structure that inhibits transcription. Targeted deletion of the *Xist* gene in cultured embryonic stem cells showed that it is required for X inactivation. Unlike most protein-coding genes on the inactive X chromosome, the *Xist* gene is actively transcribed. The *Xist* RNA-protein complexes do not diffuse to interact with the active X or other chromosomes, but remain associated with the inactive X chromosome. In contrast to *Xist*, Tsix is transcribed from the active X chromosome, not from the inactive X chromosome.

In the early female embryo, made up of embryonic stem cells capable of differentiating into all cell types (see Chapter 22), genes on both X chromosomes are transcribed, and the 40-kb Tsix lncRNA

(Figure 8-50a) is transcribed from both copies of the X chromosome. Experiments employing engineered deletions in the X-inactivation center showed that Tsix transcription prevents significant transcription of the *Xist* RNA from the complementary DNA strand. Later in development, as cells begin to differentiate, Tsix transcription is repressed on one of the X chromosomes. This repression occurs randomly in different cells on either of the X chromosomes. This inhibition of Tsix transcription determines which of the X chromosomes will be inactivated as the cells differentiate further, because inhibition of Tsix transcription allows transcription of *Xist* lncRNA to occur on that chromosome.

Recent studies indicate that *Xist* lncRNA-protein complexes first associate with regions of the X chromosome localized near the X-inactivation center in the three-dimensional, folded structure of the future inactive X (Figure 8-50c), as shown by chromosome conformation capture assays (see Figure 7-30). These initial sites of *Xist* association are in gene-rich regions of the X chromosome and are postulated to serve as entry sites where additional copies of the *Xist* lncRNA-protein complexes first bind and then spread to neighboring regions. The mechanism of spreading is not currently understood. The inactive X chromosome also becomes associated with PRC2 complexes, which catalyze the trimethylation of histone H3 lysine 27. This methylation results in association of the PRC1 complex and transcriptional repression, as discussed in the previous section. These mechanisms of transcriptional repression must be

redundant, however, because repression still occurs in the absence of the Polycomb proteins essential for the assembly of PRC1 and PRC2. At the same time, transcription of Tsix continues from the active X chromosome, which is associated with repression of *Xist* transcription from that X chromosome, and consequently prevents *Xist*-mediated repression of the active X. *Xist* and PRC1 and 2 complexes are then observed to associate with gene-poor regions of the inactive X chromosome as well as with gene-rich regions, silencing ∼1000 genes on the inactive X chromosome.

Xist RNA-protein complexes were isolated from cultured mouse embryonic stem cells undergoing the initiation phase of X inactivation. This was done by hybridizing several biotinylated oligonucleotides complementary to regions of *Xist* to nuclear extracts prepared from these cells, and then binding to a column with covalently bound streptavidin, a bacterial protein with very high affinity for biotin. Proteins eluted from this affinity column were analyzed by mass spectrometry (see Chapter 3) to identify proteins associated with *Xist* lncRNA as diagrammed in Figure 8-50d. Thus the *Xist* RNA is postulated to function as a large molecular scaffold for the assembly of a multiprotein complex. One of the proteins identified in the complex was *SMRT*, a co-repressor of the thyroid hormone nuclear receptor. During X inactivation, SMRT also interacts with the histone deacetylase HDAC3. Subsequent knockdown experiments with siRNAs directed against SMRT and HDAC3 showed that they are required for X inactivation, as are other

RNA and chromatin-binding proteins, such as SHARP, that link SMRT to *Xist* RNA (Figure 8-50d). These proteins are also required for the association of *Xist* RNA with the inactive X chromosome. These studies of *Xist* have led to the suggestion that other stable lncRNAs may function similarly as scaffolds for the assembly of other multiprotein-RNA complexes.

Shortly after X inactivation by histone deacetylation and polycomb complexes, the DNA of the inactive X chromosome becomes methylated at most of its CpG island promoters. In addition, specialized histone octamers in which histone H2A is replaced by a paralog of H2A called *macroH2A* also associate with the inactive X chromosome. DNA methylation and macroH2A contribute to the stable repression of the inactive X chromosome throughout embryogenesis and adult life.

Cis Activation by Long Noncoding RNAs

Examples of lncRNAs involved in gene activation have been characterized recently. For example, HOTTIP lncRNA, which is transcribed from the 5′ end of the *HOXA* locus, is proposed to coordinate the activation of *HOXA* genes by binding to a histone H3 lysine 4 methylase. In addition, nascent transcripts of lncRNA genes have been reported to activate transcription from promoters several kilobases away by interacting with the Mediator complex and

delivering it to the promoter by looping of the intervening chromatin.

In humans, but not in mice, the lncRNA called *XACT* associates with multiple sites along the entire length of the active X chromosome. XACT may contribute to maintenance of gene activity on that chromosome. XACT is also remarkable for being one of the longest characterized RNAs: 252 kb! It is mostly unspliced.

In *Drosophila*, equal expression of genes encoded on the X chromosome in males and females (dosage compensation) does not result from inactivating one X chromosome in females. Rather, a generalized twofold increase in transcriptional activation of genes on the single X chromosome in males is controlled by two lncRNAs, roX1 and roX2, transcribed from the X chromosome only in males. The roX1 and roX2 RNAs associate with several proteins encoded by *MSL* (male-specific-lethal) genes and spread over the X chromosome specifically, much as *Xist* lncRNA-protein complexes spread over the inactive X in mammals.

Recently, sequencing of total cellular RNA in multiple types of human cells identified roughly 15,000 human lncRNAs. Many of these lncRNAs have sequences that are evolutionarily conserved in most mammals, while about 5000 are found only in primates. This conservation of sequence strongly suggests that these lncRNAs, like *Xist*, have important functions. Many lncRNAs are expressed only in

specific cell types at specific times during development. For example, multiple lncRNAs are expressed primarily in differentiating red blood cells. Knockdown (see Figure 6-41 and Chapter 9) of several of these lncRNAs inhibits normal red blood cell development, but precisely how these lncRNAs perform their essential functions is not yet clear. The study of these conserved long noncoding RNAs and how they influence gene expression is another area of intense current investigation.

ENCODE (Encyclopedia of DNA Elements) encompasses a consortium of international research groups organized and funded by the US National Human Genome Research Institute with the goal of building a comprehensive, publicly available database of functional elements in the human genome

These elements include DNA control elements and the transcription factors that bind to them, histone post-translational modifications mapped by chromatin immunoprecipitation/next-gen sequencing (ChIP-seq) and related methods, DNase I hypersensitive sites, and regulatory lncRNAs and their sites of association in the genome, as well as newly discovered regulatory elements that control cells and circumstances in which a gene is active. Data sets from human cells and cells of model organisms that are too large to be published are also made publicly available at a site called *GEO (Gene Expression*

Omnibus) maintained by the US National Center for Bioinformatics (NCBI). Most journals that publish research based on genomic methods such as RNA-seq and ChIP-seq require that authors upload their original data to GEO. Worldwide public access to these data sets is greatly accelerating the pace of discovery in the area of gene regulation.

KEY CONCEPTS OF SECTION 8.6

Epigenetic Regulation of Transcription

- Epigenetic control of transcription refers to repression or activation that is maintained after cells replicate as the result of DNA methylation or post-translational modification of histones, especially histone methylation.
- Methylation of CpG sequences in CpG island promoters in mammals generates binding sites for a family of methyl-binding proteins (MBDs) that associate with histone deacetylases, inducing hypoacetylation of the promoter regions and transcriptional repression.
- Histone H3 lysine 9 di- and trimethylation creates binding sites for the heterochromatin-associated protein HP1, which results in condensation of chromatin and transcriptional repression. These post-translational modifications are perpetuated following chromosome replication because the methylated histones randomly associate with the daughter DNA molecules and associate with histone H3 lysine 9 methyl transferases that methylate histone 3 lysine 9 on newly synthesized histone octamers assembled on the daughter DNA.
- Polycomb complexes maintain repression of genes initially repressed by sequence-specific repressors expressed early during embryogenesis. One class of Polycomb complexes, PRC2 complexes, associates with these repressors in early embryonic cells, resulting in methylation of histone H3 lysine 27. This methylation creates binding sites for subunits in the PRC2 complex as well as for PRC1 complexes, which condense chromatin, inhibit the assembly of preinitiation complexes, and inhibit elongation. Since parent histone octamers with H3 methylated at lysine 27 are distributed to both daughter DNA molecules following DNA replication, PRC2 complexes that associate with these nucleosomes maintain histone H3 lysine 27 methylation through cell division.

- Trithorax complexes oppose repression by Polycomb complexes by methylating H3 at lysine 4 and maintaining this activating mark through chromosome replication.
- X-chromosome inactivation in female mammals requires a long noncoding RNA (lncRNA) called *Xist* that is transcribed from the X-inactivation center of one X chromosome and then spreads along the length of the same chromosome. *Xist* interacts with a co-repressor that binds a histone deacetylase and PRC2 complexes at an early stage of embryogenesis, initiating X inactivation. X inactivation is maintained throughout the remainder of embryogenesis and adult life by continued association with Polycomb complexes and DNA methylation of CpG island promoters on the inactive X.
- Some lncRNAs cause repression of genes in trans (i.e., on other chromosomes), as opposed to the cis inactivation imposed by *Xist*. Repression is initiated by their interaction with PRC2 complexes.
- Some lncRNAs are associated with gene activation. Much remains to be learned about how lncRNAs are targeted to specific chromosomal regions, but the discovery of about 15,000 nuclear lncRNAs expressed in various human cells during specific stages of their differentiation suggests that lncRNAs are central to widely used mechanisms of transcription regulation.

8.7 Other Eukaryotic Transcription Systems

We conclude this chapter with a brief discussion of transcription initiation by the other two eukaryotic nuclear RNA polymerases, Pol I and Pol III. Although these systems, and particularly their regulation, are less thoroughly understood than transcription by RNA polymerase II, they are equally fundamental to the life of eukaryotic cells. The polymerases that transcribe mitochondrial and chloroplast DNA will be discussed in Chapter 12.

Transcription Initiation by Pol I and Pol III Is Analogous to That by Pol II

The formation of transcription initiation complexes involving Pol I and Pol III is similar in some respects to assembly of Pol II initiation complexes (see Figure 8-13). However, each of the three eukaryotic nuclear RNA polymerases requires its own polymerase-specific general transcription factors and each recognizes different DNA control elements. Moreover, neither Pol I nor Pol III requires ATP hydrolysis by a DNA helicase to help melt the DNA template strands to initiate transcription, whereas Pol II does. As we discuss in Chapter 21, transcription initiation by Pol I, which synthesizes pre-rRNA, and by Pol III, which synthesizes tRNAs, 5S rRNA, and other

small stable RNAs (see Table 8-1), is tightly coupled to the rate of cell growth and proliferation.

Initiation by Pol I

The regulatory elements directing Pol I initiation are similarly located relative to the transcription start site in yeast and in mammals. A *core element* spanning the transcription start site from −40 to +5 is essential for Pol I transcription. An additional *upstream control element* extending from roughly −155 to −60 increases in vitro Pol I transcription tenfold. In humans, assembly of the Pol I preinitiation complex (Figure 8-51) is initiated by the cooperative binding of UBF (upstream binding factor) and SL1 (selectivity factor), a multisubunit factor containing TBP and four Pol I–specific TBP-associated factors (TAF_Is), to the Pol I promoter region. The TAF_I subunits interact directly with Pol I–specific subunits, directing this specific nuclear RNA polymerase to the transcription start site. TIF-1A, the mammalian homolog of *S. cerevisiae* RRN3, is another required factor, as are the abundant nuclear protein kinase CK2 (casein kinase 2), nuclear actin, nuclear myosin, the protein deacetylase SIRT7, and topoisomerase I, which prevents DNA supercoils (see Figure 5-8) from forming during rapid Pol I transcription of the 14-kb transcription unit.

FIGURE 8-51 Transcription of the rRNA precursor RNA by RNA polymerase I. *Top*: Electron micrograph of RNA-protein complexes transcribed from repeated rRNA genes. *Middle:* A single Pol I transcription unit. Enhancers that stimulate Pol I transcription from a single transcription start site are represented by blue boxes. Pol I transcription termination sites (T_0, $T_1 - T_{10}$) bound by the Pol I–specific termination factor TTF-1 are shown as red rectangles. pRNA indicates transcription of the noncoding pRNA required for transcriptional silencing. The black arrow indicates the start site of the primary transcript. Regions of DNA shown as parallel black lines are contained in the primary transcript, but are removed and degraded during rRNA processing. *Bottom:* The core promoter element and upstream control element are shown with the location of Pol I and its general transcription factors UBF, SL1, and TIF-1A represented, as well as other proteins required for Pol I elongation and control.

Transcription of the 14-kb precursor of 18S, 5.8S, and 28S rRNAs (see Chapter 9) is regulated to coordinate ribosome synthesis with cell growth and division. This coordination is achieved in several ways: regulation of the activities of Pol I initiation factors by post-translational modifications, including phosphorylation and acetylation; control of the rate of Pol I elongation; and control of the number of rRNA genes that are transcriptionally active by epigenetic mechanisms that assemble inactive copies into heterochromatin. At active rRNA genes, transcription terminates at terminator sequencs T_0 and T_1, T_2, T_3, … T_{10}, positioned as shown in Figure 8-51. This nonsymmetrical sequence functions to terminate Pol I transcription only when it is in the correct orientation. The terminator sequences are bound by a termination factor that causes termination and Pol I release from the template.

Switching between the active and heterochromatic silent states of rRNA genes is accomplished by a multisubunit chromatin-remodeling complex called *NoRC* (*No* for nucleolus, the site of rRNA transcription within nuclei). NoRC localizes a nucleosome over the Pol I transcription start site, blocking preinitiation complex assembly. It also interacts with a DNA methyl transferase that methylates a critical CpG in the upstream control element, thus inhibiting binding by UBF. NoRC also interacts with histone deacetylases and with histone methyl transferases that di- and trimethylate histone H3 lysine 9, creating binding sites for heterochromatic HP1. Moreover, a roughly 250-nt noncoding RNA

called *pRNA* (promoter-associated RNA) transcribed by Pol I from about 2 kb upstream of the rRNA transcription unit (red arrow in Figure 8-51) is bound by a subunit of NoRC and is required for transcriptional silencing by assembly of the gene into heterochromatin. The pRNA is believed to target NoRC to Pol I promoter regions by forming an RNA:DNA triplex with the T_0 terminator sequence. This creates a binding site for the DNA methyl transferase DNMT3b, which methylates the critical CpG in the upstream promoter element.

Initiation by Pol III

Unlike promoters for protein-coding genes and pre-rRNA genes, the promoter regions of tRNA and 5S-rRNA genes lie entirely within the transcribed sequence (Figure 8-52a, b). Two such *internal* promoter elements, termed the *A box* and the *B box*, are present in all tRNA genes. These highly conserved sequences not only function as promoters but also encode two invariant portions of eukaryotic tRNAs that are required for protein synthesis. In 5S-rRNA genes, a single internal control region, the *C box*, acts as a promoter.

FIGURE 8-52 Transcription-control elements in genes transcribed by RNA polymerase III. Both tRNA (a) and 5S-rRNA (b) genes contain internal promoter elements (yellow) located downstream from the start site and named A, B, and C boxes, as indicated. Assembly of transcription initiation complexes on these genes begins with the binding of Pol III–specific general transcription factors TFIIIA, TFIIIB, and TFIIIC to these control elements. Green arrows indicate strong, sequence-specific protein-DNA interactions. Blue arrows indicate interactions between general

transcription factors. Purple arrows indicate interactions between general transcription factors and Pol III. (c) Transcription of the U6 snRNA gene in mammals is controlled by an upstream promoter with a TATA box bound by the TBP subunit of a specialized form of TFIIIB with an alternative BRF subunit and an upstream regulatory element called the *PSE* bound by a multisubunit factor called $SNAP_C$. See L. Schramm and N. Hernandez, 2002, *Genes Dev.* **16**:2593.

Three general transcription factors are required for Pol III to initiate transcription of tRNA and 5S-rRNA genes in vitro. Two multimeric factors, TFIIIC and TFIIIB, participate in initiation at both tRNA and 5S-rRNA promoters, while a third factor, TFIIIA, is required for initiation at 5S-rRNA promoters. As with assembly of Pol I and Pol II initiation complexes, the Pol III general transcription factors bind to promoter DNA in a defined sequence.

The N-terminal half of one TFIIIB subunit, called *BRF* (for TFII*B*-*r*elated *f*actor), is similar in sequence to TFIIB (a Pol II factor). This similarity suggests that BRF and TFIIB perform a similar function in initiation, namely, to assist in separating the template DNA strands at the transcription start site. Once TFIIIB has bound to either a tRNA or a 5S-rRNA gene, Pol III can bind and initiate transcription in the presence of ribonucleoside triphosphates. The BRF subunit of TFIIIB interacts specifically with one of the polymerase subunits unique to Pol III, accounting for initiation by this specific nuclear RNA polymerase.

Another of the three subunits composing TFIIIB is TBP, which we can now see is a component of a general transcription factor for all three eukaryotic nuclear RNA polymerases. The finding that TBP participates in transcription initiation by Pol I and Pol III was surprising, since the promoters recognized by these enzymes often do not contain TATA boxes. Nonetheless, in the case of Pol III transcription, the TBP subunit of TFIIIB interacts with DNA about 30 bp upstream of the transcription start site. The protein-DNA interaction is similar to the way TBP interacts with TATA boxes.

Pol III also transcribes genes for small stable RNAs with upstream promoters containing a TATA box. One example is the gene for U6 snRNA, which is involved in pre-mRNA splicing (see Chapter 9). In mammals, this gene contains an upstream promoter element called the *PSE* in addition to the TATA box (Figure 8-52c). The PSE is bound by a multisubunit complex called $SNAP_C$, while the TATA box is bound by the TBP subunit of a specialized form of TFIIIB containing an alternative BRF subunit.

MAF1 is a specific inhibitor of Pol III transcription that functions by interacting with the BRF subunit of TFIIIB and with Pol III. Its function is regulated by controlling its import from the cytoplasm into the nucleus. MAF1 transport into the nucleus is activated by phosphorylations of MAF1 in response to the mTORC1 protein kinase that responds to cell stress and nutrient deprivation (see Chapters 16 and 25). In mammals, Pol III transcription is also

repressed by the tumor suppressors p53 and the retinoblastoma (Rb) family of proteins. In humans, there are two genes encoding the Pol III subunit RPC32. One of these is expressed specifically in replicating cells, and its forced expression can contribute to oncogenic transformation of cultured human fibroblasts, suggesting that altered regulation of transcription by Pol III with this subunit is oncogenic.

KEY CONCEPTS OF SECTION 8.7

Other Eukaryotic Transcription Systems

- The process of transcription initiation by Pol I and Pol III is similar to that by Pol II but requires different general transcription factors, is directed by different promoter elements, and does not require hydrolysis of ATP β-γ phosphodiester bonds to separate the DNA strands at the start site as Pol II transcription does.
- Pol I transcribes only a single RNA, the 45S precursor of 18S, 5.8S, and 28S rRNA, from multiple copies of the pre-rRNA gene.
- Pol III transcribes tRNAs from promoters within the genes that encode the tRNA regions common to all tRNAs. This internal promoter is bound by transcription factor TFIIIC, which in turn binds TFIIIB, a multisubunit factor that includes the TATA box–binding protein, TBP, which associates with the tRNA gene about 30 bp upstream of the transcription start site.
- Pol III transcribes 5s rRNA directed by a promoter within the 5S-rRNA coding region that is bound by transcription factor TFIIIA. TFIIIA then associates with TFIIIC and TFIIIB, which interact with Pol III in a manner similar to their interactions in tRNA transcription.
- Additional small stable RNAs, several with as yet unknown functions, are transcribed by Pol III as directed by TBP-containing transcription factors that bind immediately upstream of the genes (see Figure 8-52).
- Pol III transcription is regulated by a specific inhibitor, MAF1, whose transport from the cytoplasm into the nucleus is controlled in response to nutrient availability.

Review the Concepts

1. What types of genes are transcribed by RNA polymerases I, II, and III? Design an experiment to determine whether a specific gene is transcribed by RNA polymerase II.
2. The CTD of the largest subunit of RNA polymerase II can be phosphorylated at multiple serine residues. What are the conditions that lead to the phosphorylated versus nonphosphorylated RNA polymerase II CTD?
3. What do TATA boxes, initiators, and CpG islands have in common? Which was the first of these to be identified? Why?
4. Describe the methods used to identify the location of transcription-control elements in promoter-proximal regions of genes.

5. What is the difference between a promoter-proximal element and a distal enhancer? What are the similarities?
6. Describe the methods used to identify the location of DNA-binding proteins in the regulatory regions of genes.
7. Describe the structural features of transcription activator and repressor proteins.
8. Give two examples of how gene expression may be repressed without altering the coding sequence.
9. Using CREB and nuclear receptors as examples, compare and contrast the structural changes that take place when these transcription factors bind to their co-activators.
10. What general transcription factors associate with an RNA polymerase II promoter in addition to the polymerase? In what order do they bind in vitro? What structural change occurs in the DNA when an "open" transcription initiation complex is formed?
11. Expression of recombinant proteins in yeast is an important tool for biotechnology companies that produce new drugs for human use. In an attempt to get a new gene *X* expressed in yeast, a researcher has integrated gene *X* into the yeast genome near a telomere. Will this strategy result in good expression of gene *X*? Why or why not? Would the outcome of this experiment differ if the experiment had been performed in a yeast line containing mutations in the H3 or H4 histone tails?
12. You have isolated a new protein called *STICKY*. You can predict from comparisons with other known proteins that STICKY contains a bHLH domain and a Sin3-interacting

domain. Predict the function of STICKY and explain the importance of these domains in STICKY function.

13. Lower eukaryotes such as yeast have transcription-control elements called *upstream activating sequences*. What are the comparable sequences found in higher eukaryotic species?
14. You are curious to identify the region of the gene *X* sequence that serves as an enhancer for gene expression. Design an experiment to investigate this issue.
15. Some organisms have mechanisms in place that will override transcription termination. One such mechanism using the Tat protein is employed by the HIV retrovirus. Explain why Tat is therefore a good target for HIV vaccination.
16. Upon identification of the DNA-regulatory sequence responsible for translating a given gene, you note that it is enriched with CG sequences. Is the corresponding gene likely to be a highly expressed transcript?
17. Name four major classes of DNA-binding proteins that are responsible for controlling transcription, and describe their structural features.

9.6 Nuclear Bodies Are Functionally Specialized Nuclear Domains

---

In the previous chapter, we saw that most genes are regulated at the first step in gene expression — transcription — by regulating the assembly of the transcription preinitiation complex on a promoter-DNA sequence and regulating transcription elongation in the promoter-proximal region. Once transcription has been initiated, synthesis of the encoded RNA requires that RNA polymerase transcribe the entire gene and not terminate prematurely. Moreover, the initial primary transcripts produced from eukaryotic genes must undergo various processing reactions to yield the corresponding functional RNAs. For mRNAs, the 5′ cap structure necessary for translation must be added (see Figure 5-26), introns must be spliced out of **pre-mRNAs** (Table 9-1), and the 3′ end must be polyadenylated (see Figure 5-27). Once formed in the nucleus, mature, functional RNAs are exported to the cytoplasm as components of ribonucleoproteins. Processing of mRNAs in the nucleus, their export from the nucleus, and their transport to specific loci in the cytoplasm offer opportunities for further regulating gene expression after the initiation of transcription.

TABLE 9-1 • RNAs Discussed in Chapter 9

mRNA	Fully processed messenger RNA with $5'$ cap, introns removed by RNA splicing, and a poly(A) tail.
pre-mRNA	An mRNA precursor containing introns and not cleaved at the poly(A) site.
hnRNA	Heterogeneous nuclear RNAs. These RNAs include pre-mRNAs and RNA-processing intermediates containing one or more introns.
snRNA	Five small nuclear RNAs that function in the removal of introns from pre-mRNAs by RNA splicing, plus two small nuclear RNAs that substitute for the first two at rare introns.
pre-tRNA	A tRNA precursor containing additional transcribed bases at the $5'$ and $3'$ ends compared with the mature tRNA. Some pre-tRNAs also contain an intron in the anticodon loop.
pre-rRNA	The precursor to mature 18S, 5.8S, and 28S ribosomal RNAs. The mature rRNAs are processed from this long precursor RNA molecule by cleavage, removal of bases from the ends of the cleaved products, and modification of specific bases.
snoRNA	Small nucleolar RNAs. These RNAs base-pair with complementary regions of the pre-rRNA molecule, directing cleavage of the RNA chain and modification of bases during maturation of the rRNAs.
siRNA	Short interfering RNAs, ~ 22 bases long, that are each perfectly complementary to a sequence in an mRNA. Together with associated proteins, siRNAs cause cleavage of the target RNA, leading to its rapid degradation.
miRNA	MicroRNAs, ~ 22 bases long, that base-pair extensively, but not completely, with mRNAs, especially over bases 2 to 7 at the $5'$ end of the miRNA (the “seed” sequence). This pairing inhibits translation of the target mRNA and targets it for degradation.

Recently, the vast amount of sequence data of human mRNAs expressed in different tissues and at various times during embryogenesis and cellular differentiation has revealed that ~95 percent of human genes give rise to alternatively spliced mRNAs. These alternatively spliced mRNAs encode related proteins with differences in sequences limited to specific functional domains. In many cases, alternative RNA splicing is regulated to meet the need for a specific protein isoform in a specific cell type. Given the complexity of pre-mRNA splicing, it is not surprising that mistakes are occasionally made, giving rise to mRNA precursors with improperly spliced exons. However, eukaryotic cells have evolved RNA-surveillance mechanisms that prevent the transport of incorrectly processed RNAs to the cytoplasm or lead to their degradation if they are transported.

Additional control of gene expression can occur in the cytoplasm. In the case of protein-coding genes, for instance, the amount of protein produced depends on the stability of the corresponding mRNAs in the cytoplasm and the rate of their translation. For example, during an immune response, lymphocytes communicate by secreting polypeptide hormones called *cytokines* that signal neighboring lymphocytes through cytokine receptors that span their plasma membranes (Chapter 24). It is important for lymphocytes to synthesize and secrete cytokines in short bursts. This is possible because cytokine mRNAs are extremely unstable. Consequently, the concentration of the mRNA in the cytoplasm falls rapidly once its

synthesis is stopped. In contrast, mRNAs encoding proteins required in large amounts that function over long periods, such as ribosomal proteins, are extremely stable so that multiple polypeptides can be transcribed from each mRNA.

In addition to regulation of pre-mRNA processing, nuclear export, and translation, the cellular locations of many, if not most, mRNAs are regulated so that newly synthesized protein is concentrated where it is needed. Particularly striking examples of this occur in the nervous systems of multicellular animals. Some neurons in the human brain generate more than 1000 separate synapses with other neurons. During the process of learning, synapses that fire more frequently than others increase in size many times, while other less active synapses made by the same neuron do not. This can occur because mRNAs encoding critical synapse proteins are stored at all synapses, but translation of these localized, stored mRNAs is regulated at each synapse independently by the frequency at which that synapse fires. In this way, synthesis of synapse-associated proteins can be regulated independently at each of the many synapses made by the same neuron (see Chapter 23).

Another type of gene regulation involves microRNAs (miRNAs), which regulate the stability and translation of specific target mRNAs to which they base pair in multicellular animals and plants. Analyses of these short miRNAs in various human tissues indicate that ~1900 miRNAs are expressed in the multiple types of human

cells. Although some have recently been discovered to function through inhibition of target gene expression in the appropriate tissue and at the appropriate time in development, the functions of the vast majority of human miRNAs are unknown and are the subject of a growing area of research. A closely related process called *RNA interference (RNAi)* is used by some organisms to degrade viral RNAs following infection and in the degradation of transposon-encoded RNAs. RNAi is extensively utilized in biomedical research: designed short interfering RNAs (siRNA) can be used to inhibit the translation of specific mRNAs experimentally by a process called *RNA knockdown*. This makes it possible to inhibit the function of any desired gene, even in organisms that are not amenable to classic genetic methods for isolating mutants.

We refer to all the mechanisms that regulate gene expression following transcription as *post-transcriptional gene control* (Figure 9-1). Because the stability and translation rate of an mRNA contribute to the amount of protein expressed from a gene, these post-transcriptional processes are important components of gene control. Indeed, the protein output of a gene is regulated at every step in the life of an mRNA from the initiation of its synthesis to its degradation. Thus genetic regulatory processes act on RNA as well as DNA. In this chapter, we consider the events that occur in the processing of mRNA following transcription initiation and promoter-proximal elongation as well as mechanisms discovered that regulate these steps in mRNA processing. In the last section, we

briefly discuss the processing of primary transcripts produced from genes encoding rRNAs and tRNAs.

FIGURE 9-1 Overview of RNA processing and post-transcriptional gene control. Nearly all cytoplasmic RNAs are processed from primary transcripts in

the nucleus before they are exported to the cytoplasm. Major processing steps are diagrammed for RNAs transcribed by RNA polymerases I, II, and III. For protein-coding genes transcribed by RNA polymerase II, post-transcriptional gene control can be exerted through (step **1**) the choice of alternative exons during pre-mRNA splicing and (step **2**) the choice of alternative poly(A) sites. Improperly processed mRNAs are blocked from export to the cytoplasm and degraded (step **3**) by a large complex called the *exosome* that contains internal ribonucleases. Once exported to the cytoplasm (step **4**), translation initiation factors bind to the mRNA $5'$-cap cooperatively with poly(A)-binding protein C bound to the poly(A) tail and initiate translation (see Figure 5-36) (step **5**). (Step **6**) mRNA is degraded in the cytoplasm by deadenylation and decapping followed by degradation by cytoplasmic exosomes. Much of this mRNA degradation takes place in regions of the cytoplasm with high RNA concentration called "P bodies." The degradation rate of each mRNA is controlled, thereby regulating the mRNA concentration and, consequently, the amount of protein translated. Some mRNAs are synthesized without long poly(A) tails. Their translation is regulated by (step **7**) controlling the synthesis of a long poly(A) tail by a cytoplasmic poly(A) polymerase. Translation is also regulated by other mechanisms including miRNAs (step **8**). When expressed, these ~ 22-nucleotide RNAs inhibit translation of mRNAs to which they hybridize, usually in the $3'$ untranslated region. tRNAs and rRNAs are also synthesized as precursor RNAs that must be (step **9a**, **b**) processed before they are functional. Regions of precursors cleaved from the mature RNAs are degraded by nuclear exosomes (step **10**). See J. Houseley et al., 2006, *Nat. Rev. Mol. Cell Biol.* **7**:529.

9.1 Processing of Eukaryotic Pre-mRNA

In this section, we take a closer look at how eukaryotic cells convert the initial primary transcript synthesized by RNA polymerase II into a functional mRNA. Three major events occur during the process: **5′ capping**, **3′ cleavage/polyadenylation**, and **RNA splicing** (Figure 9-2). Adding these specific modifications to the 5′ and 3′ ends of the pre-mRNA is important to protect it from enzymes that quickly digest uncapped RNAs generated by RNA processing, such as spliced-out introns and RNA transcribed downstream from a polyadenylation site. The 5′ cap and 3′ poly(A) tail distinguish pre-mRNA molecules from the many other kinds of RNAs in the nucleus. Pre-mRNA molecules (see Table 9-1) are bound by nuclear proteins that function in mRNA export to the cytoplasm. After mRNAs are exported to the cytoplasm, they are bound by a set of cytoplasmic proteins that stimulate translation and are critical for mRNA stability in the cytoplasm. Prior to nuclear export, introns must be removed to generate the correct coding region of the mRNA. In vertebrates, including humans, **alternative splicing** is intricately regulated in order to include alternative functional domains in closely related proteins, producing a considerable expansion of the proteome of these organisms.

FIGURE 9-2 Overview of mRNA processing in eukaryotes. Shortly after RNA polymerase II initiates transcription at the first nucleotide of the first exon of a gene, the 5′ end of the nascent RNA is capped with 7-methylguanylate (step 1). Transcription by RNA polymerase II terminates at any one of multiple termination sites downstream from the poly(A) site, which is located at the 3′ end of the final exon. After the primary transcript is cleaved at the poly(A) site (step 2), a string of adenosine (A) residues is added (step 3). The poly(A) tail contains ~250 A residues in mammals, ~150 in insects, and ~100 in yeasts. For short primary transcripts with few introns, splicing (step 4) usually follows cleavage and polyadenylation, as shown. For large genes with multiple introns, introns often are spliced out of the nascent RNA during its transcription, i.e., before transcription of the gene is complete. Note that the 5′ cap and sequence adjacent to the poly(A) tail are retained in mature mRNAs. The diagram shown represents processing of human β-globin RNA.

The pre-mRNA processing events of capping, splicing, and polyadenylation occur in the nucleus as the nascent mRNA precursor is being transcribed. Thus pre-mRNA processing is *co-transcriptional*: it occurs while the RNA is being transcribed. As the RNA emerges from the surface of RNA polymerase II, its 5′ end is

immediately modified by the addition of the 5′ cap structure found on all mRNAs (see Figure 5-26). As the nascent pre-mRNA continues to emerge from the surface of the polymerase, it is immediately bound by members of a complex group of abundant RNA-binding proteins called *hnRNP proteins* that assist in RNA splicing and export of the fully processed mRNA through nuclear pore complexes into the cytoplasm. Some of these proteins remain associated with the mRNA in the cytoplasm, but most either remain in the nucleus or shuttle back into the nucleus shortly after the mRNA is exported to the cytoplasm. Cytoplasmic RNA-binding proteins are exchanged for the nuclear ones. Consequently, eukaryotic mRNAs never occur as free RNA molecules in the cell but are always associated with protein as ***ribonucleoprotein (RNP) complexes***.

Nuclear nascent *pre-mRNAs* associated with hnRNP proteins are referred to as *pre-mRNPs.* They are capped and spliced as they are transcribed. Then, following cleavage and polyadenylation at the 3′ end, they are referred to as *nuclear mRNPs.* Following the exchange of proteins that accompany export to the cytoplasm, they are called *cytoplasmic mRNPs.* Although we frequently refer to pre-mRNAs and mRNAs, it is important to remember that in eukaryotes they are always associated with proteins as RNP complexes.

The 5′ Cap Is Added to Nascent RNAs Shortly After Transcription Initiation

As the nascent RNA transcript emerges from the RNA exit channel of RNA polymerase II and reaches a length of ~25 nucleotides, a protective cap composed of 7-methylguanosine and methylated riboses is added to the 5′ end of eukaryotic mRNAs (see Figure 5-26). The 5′ *cap* marks RNA molecules as mRNA precursors and protects them from RNA-digesting enzymes (5′-exoribonucleases) in the nucleus and cytoplasm. This initial step in RNA processing is catalyzed by a dimeric capping enzyme, which associates with the phosphorylated carboxyl-terminal domain (CTD) of RNA polymerase II. Recall that the CTD becomes phosphorylated by the TFIIH general transcription factor at multiple serines at the 5 position in the CTD heptapeptide (seven residue) repeat during transcription initiation (see Figure 8-7(b) red arrow, Figure 8-8). Binding to the phosphorylated CTD stimulates the activity of the capping enzymes so that they target RNAs containing a 5′-triphosphate that emerge from RNA polymerase II and not RNAs transcribed by RNA polymerases I or III, which do not have a CTD. This is important because pre-mRNA synthesis accounts for only ~80 percent of the total RNA synthesized in replicating cells. The other 20 percent is pre-ribosomal RNA (**pre-rRNA**), which is transcribed by RNA polymerase I, and 5S rRNA, tRNAs, and other stable small RNAs transcribed by RNA polymerase III.

One subunit of the capping enzyme removes the γ-phosphate from the 5′ end of the nascent RNA (Figure 9-3). Another domain of this subunit transfers the GMP moiety from GTP to the 5′-diphosphate of

the nascent transcript, creating the unusual guanosine 5′, 5′-triphosphate ester structure. In the final steps, separate enzymes transfer methyl groups from *S*-adenosylmethionine to the N_7 position of the guanine and one or two of the 2′ oxygens of the ribose at the 5′ end of the nascent RNA.

FIGURE 9-3 Synthesis of 5′-cap on eukaryotic mRNAs. The 5′ end of a nascent RNA contains a 5′-triphosphate from the initiating NTP. The γ-phosphate is removed in the first step of capping, while the remaining α- and β-phosphates (orange) remain

associated with the cap. The third phosphate of the 5′,5′-triphosphate ester is derived from the α-phosphate of the GTP that donates the guanine. The methyl donor for methylation of the cap guanine and the first one or two riboses of the mRNA is S-adenosylmethionine (S-Ado-Met). See S. Venkatesan and B. Moss, 1982, *Proc. Nat'l. Acad. Sci. USA* **79**:304.

Considerable evidence indicates that capping of the nascent transcript is coupled to elongation by RNA polymerase II so that all transcripts generated by this polymerase are capped during the earliest phase of elongation. As discussed in Chapter 8, during the initial phase of transcription in metazoans, the polymerase elongates the nascent transcript very slowly due to association of NELF (*n*egative *el*ongation *f*actor) with a complex of RNA polymerase II and DSIF in the promoter-proximal region (see Figure 8-3 *bottom*, Figure 8-15a). Once the 5′ end of the nascent RNA is capped, phosphorylation of the RNA polymerase CTD at position 2 in the heptapeptide repeat and of NELF and DSIF by the cyclin T-CDK9 protein kinase causes the release of NELF (Figure 8-16). This allows the PAF elongation complex to associate with RNA polymerase II (Figure 8-15b), which then enters into a faster mode of elongation that rapidly transcribes away from the promoter. The net effect of this mechanism is that the polymerase waits for the nascent RNA to be capped before elongating at a rapid rate.

Chain Elongation by RNA Polymerase II Is Coupled to the Presence of RNA

Processing Factors

How is RNA processing coupled with the transcription of a pre-mRNA so that only Pol II transcripts are subjected to 5′ capping, RNA splicing, and polyadenylation? The key lies in the long carboxyl-terminal domain (CTD) of RNA polymerase II, which, as discussed in Chapter 8, is composed of multiple repeats of a heptapeptide sequence. When fully extended, the CTD domain in the yeast enzyme is about 65 nm long (Figure 9-4); the CTD in human RNA polymerase II is about twice as long. The remarkable length of the CTD apparently allows multiple proteins to associate simultaneously with a single RNA polymerase II molecule. As mentioned earlier, the enzymes that add the 5′ cap to nascent transcripts associate with the CTD phosphorylated on multiple serines at the fifth position in the heptapeptide repeat (Ser-5) during or shortly after transcription initiation by a subunit of TFIIH. In addition, RNA splicing and polyadenylation factors associate with the phosphorylated CTD. As a consequence, these processing factors are present at *high local concentrations* when splice sites and poly(A) signals are transcribed by the polymerase, enhancing the rate and specificity of RNA processing. In a reciprocal fashion, the association of hnRNP proteins, discussed below, with the nascent RNA enhances the interaction of RNA polymerase II with elongation factors such as DSIF and cyclin T-CDK9 (also called “P-TEFb”) (Figure 8-16), increasing the rate of transcription. As a consequence, the rate of transcription is coordinated with the rate of nascent RNA

association with hnRNP proteins and RNA-processing factors. This mechanism ensures that a pre-mRNA is not synthesized unless the machinery for processing it is properly positioned.

FIGURE 9-4 Schematic diagram of the length of the RNA polymerase II CTD relative to the globular domain of the polymerase. The length of the yeast RNA polymerase II carboxyl-terminal domain (CTD) and the linker region that connects it to the polymerase is shown relative to the globular domain of the polymerase. The CTD of mammalian RNA polymerase II is twice as long. In its extended form, the CTD can associate with multiple RNA-processing factors simultaneously. See P. Cramer, D. A. Bushnell, and R. D. Kornberg, 2001, *Science* **292**:1863.

A Diverse Set of Proteins with Conserved RNA-Binding Domains Associate with Pre-mRNAs

As noted earlier, neither nascent RNA transcripts from protein-coding genes nor the intermediates of mRNA processing, collectively referred to as *pre-mRNA*, exist as free RNA molecules in the nuclei of eukaryotic cells. From the time nascent transcripts first emerge from RNA polymerase II until mature mRNAs are transported into the cytoplasm, the RNA molecules are associated with nuclear proteins. The most abundant of these are the major protein components of *heterogeneous ribonucleoprotein particles (hnRNPs),* which contain *heterogeneous nuclear RNA (hnRNA),* a

collective term referring to pre-mRNA- and mRNA-processing intermediates of various sizes. These hnRNP proteins contribute to further steps in RNA processing, including splicing, polyadenylation, and export through nuclear pore complexes to the cytoplasm.

Researchers identified hnRNP proteins by first exposing cultured cells to high-dose UV irradiation, which causes covalent cross-links to form between RNA bases and closely associated proteins. Chromatography of nuclear extracts from treated cells on an oligo-dT cellulose column, which binds RNAs with a poly(A) tail, was used to recover the proteins that had become cross-linked to nuclear polyadenylated RNA. These included a complex set of abundant hnRNP proteins ranging in size from ~30 to ~120 kDa, collectively referred to as *hnRNP proteins*.

Like transcription factors, most hnRNP proteins have a modular structure. They contain one or more *RNA-binding domains* and at least one other domain, often an intrinsically disordered protein domain (see Figure 3-13 and associated text), that interacts with other proteins. Several different classes of RNA-binding domains are associated with hnRNP proteins, identified by testing deletion mutants for their ability to bind RNA.

Functions of hnRNP Proteins

These RNA-associated proteins have three key functions. First, the association of pre-mRNAs with the RNA-binding domains of hnRNP proteins prevents the pre-mRNAs from forming short secondary structures dependent on base pairing of closely spaced, short complementary regions. Pre-mRNAs associated with hnRNP proteins present a more uniform substrate for subsequent processing steps than would free, unbound pre-mRNAs, in which each mRNA forms a unique secondary structure due to its specific sequence. The RNA-binding domains of hnRNPs usually interact preferentially with short RNA sequences of three to four bases.

The second key function is in regulating pre-mRNA splicing. In mammals, alternatively spliced mRNAs are expressed from almost all genes (~95 percent). Regulation of the use of one or the other of the alternative splice sites present in a pre-mRNA transcribed from these genes depends in part on binding of specific hnRNP proteins. The binding of hnRNP proteins to a pre-mRNA near an RNA splice site can inhibit binding of factors required for pre-mRNA splicing and hence direct splicing to an alternative splice site (see below).

The third function is in mRNA transport. Cell-fusion experiments have shown that some hnRNP proteins remain localized in the nucleus, whereas others cycle in and out of the cytoplasm. This was the initial evidence suggesting that the hnRNPs that cycle in and out of the nucleus function in the transport of mRNA into the cytoplasm (Figure 9-5).

FIGURE 9-5 Human hnRNP A1 protein can cycle in and out of the nucleus, but human hnRNP C protein cannot. Cultured HeLa cells and *Xenopus* cells were fused by treatment with polyethylene glycol, producing heterokaryons containing nuclei from each cell type. Cyclohexamide was added immediately after fusion to prevent protein synthesis. After 2 hours, the cells were fixed and stained with fluorescent-labeled antibodies specific for human hnRNP C (green) and A1 proteins (red). These antibodies do not bind to the homologous Xenopus proteins. (a) A fixed preparation viewed by phase-contrast microscopy includes one unfused HeLa cell (arrowhead) and one unfused Xenopus cell (dotted arrow). Note that the nucleus in the Xenopus cell contains one prominent nucleolus and is more oval in shape than the round HeLa cell nucleus containing three nuclei. A fused heterokaryon (solid arrow) in this micrograph contains a round HeLa cell nucleus to the right of the oval-shaped Xenopus nucleus with one nucleolus. (b, c) When the same preparation was viewed by fluorescence microscopy, human hnRNP C protein appeared green and human hnRNP A1 protein appeared red. Note that the unfused Xenopus cell on the left is unstained, confirming that the antibodies are specific for the human proteins. In the heterokaryon, human hnRNP C protein (green) appears only in the HeLa-cell nucleus (b), whereas the human A1 protein (red) appears in both the HeLa-cell nucleus and the Xenopus nucleus in the heterokaryon (c). Since protein synthesis was blocked after cell fusion, some of the human hnRNP A1 protein must have left the HeLa-cell nucleus, moved through the cytoplasm, and entered the Xenopus nucleus in the heterokaryon.

RNA-Binding Domains

The *RNA recognition motif (RRM)* is the most common RNA-binding domain in hnRNP proteins. This ~80-residue domain, which occurs in many other RNA-binding proteins, contains two highly conserved sequences (RNP1 and RNP2) that are found across organisms ranging from yeast to human — indicating that like many DNA-binding domains, they arose early in eukaryotic evolution.

Structural analyses have shown that the RRM domain consists of a four-stranded β sheet flanked on one side by two α helices (Figure 9-6a). To interact with the negatively charged RNA phosphates, the β sheet forms a positively charged surface. The conserved RNP1 and RNP2 sequences lie side by side on the two central β strands, and their side chains make multiple contacts with a single-stranded region of RNA that lies across the surface of the β sheet. This is seen in the x-ray crystal structure of the two RRM domains of *Drosophila* Sex-lethal protein (Sxl) bound to its specific site in RNA (Figure 9-6b), and the two RRM domains of human polypyrimidine tract-binding protein (PTB) bound to its specific RNA (Figure 9-6c). Sxl and PTB are examples of the strikingly different orientations of RRM domains in different hnRNPs.

FIGURE 9-6 Structure of the RRM domain and its interaction with RNA. (a) Diagram of the RRM domain showing the two α helices (green) and four β strands (red) that characterize this motif. The conserved RNP1 and RNP2 regions are located in the two central β strands. (b) Surface representation of the two RRM domains in *Drosophila* Sex-lethal (Sxl) protein, which together bind a continuous nine-base sequence in transformer pre-mRNA (yellow). In both (b) and (c), positively charged regions are shown in shades of blue; negatively charged regions, in shades of red; RNA is yellow. The two RRMs in Sxl are oriented like the two parts of an open pair of castanets, with the β sheets of the RRMs facing toward each other. The pre-mRNA is bound to the surfaces of the positively charged β sheets, making most of its contacts with the RNP1 and RNP2 regions of each RRM. (c) Strikingly different orientation of RRM domains in the polypyrimidine tract-binding protein (PTB), illustrating that RRMs are oriented in different relative positions in different hnRNPs. p(Y)-tract is a polypyrimidine tract. In PTB, the two RRMs associate through their α helices, so that the positively charged β sheets face away from each other, upward for RRM3 and downward for RRM4. The structure of CUCUCU single-stranded RNA bound to each of the two RRMs was determined, explaining how PTB can bind to two tracts of six pyrimidines in a single RNA if they are separated by a loop of ~ 15 or more nucleotides. This ability of PTB to form a small loop in a pre-mRNA probably contributes to its ability to function as a splicing repressor at exons where the upstream $3'$ splice site or the downstream $5'$ splice site is flanked by two polypyrimidine tracts. Part (a) See K. Nagai et al., 1995, *Trends Biochem. Sci.* **20**:235.

[Part (b) Data from N. Harada et al., 1999, *Nature* **398**:579. Part (c) Data from F. C. Oberstrass et al., 2006, *Science* **309**:2054.]

The 45-residue *KH domain* is found in the hnRNP K protein and several other RNA-binding proteins. The three-dimensional

structure of representative KH domains is similar to that of the RRM domain but smaller, consisting of a three-stranded β sheet supported from one side by two α helices. Nonetheless, the KH domain interacts with RNA much differently than does the RRM domain. RNA binds to the KH domain by interacting with a hydrophobic surface formed by the α helices and one β strand. The *RGG box,* another RNA-binding motif found in hnRNP proteins, contains five Arg-Gly-Gly (RGG) repeats with several interspersed aromatic amino acids. Its arginine-rich nature is similar to the RNA-binding domains of the HIV Tat protein. KH domains and RGG repeats are often interspersed in two or more sets in a single RNA-binding protein.

Splicing Occurs at Short, Conserved Sequences in Pre-mRNAs via Two Transesterification Reactions

During formation of a mature, functional mRNA, the **introns** are removed and **exons** are spliced together. For short transcription units, RNA splicing usually follows cleavage and polyadenylation of the 3′ end of the primary transcript, as depicted for β-globin in Figure 9-2. However, for long transcription units containing multiple exons, splicing of exons in the nascent RNA begins before transcription of the gene is complete.

Early pioneering research on the nuclear processing of mRNAs revealed that mRNAs are initially transcribed as much longer RNA molecules than the mature mRNAs in the cytoplasm. It was also shown that RNA sequences near the 5′ cap added shortly after transcription initiation are retained in the mature mRNA and that RNA sequences near the polyadenylated 3′ end of mRNA processing intermediates in hnRNA also are retained in the mature mRNA in the cytoplasm. How could an RNA be shorter than the primary transcript, but have the same 5′ and 3′ ends? The solution to this apparent conundrum came from the discovery of introns by electron microscopy of RNA-DNA hybrids of adenovirus DNA and the mRNA-encoding hexon, a major virion capsid protein (Figure 9-7). Other studies revealed nuclear viral RNAs that were colinear with the viral DNA (primary transcripts) and RNAs with one or two of the introns removed (processing intermediates). These results, together with the earlier findings that the 5′ cap and 3′ poly(A) tail at each end of long mRNA precursors are retained in shorter mature cytoplasmic mRNAs, led to the realization that introns are removed from primary transcripts as exons are spliced together.

EXPERIMENTAL FIGURE 9-7 Electron microscopy of mRNA-template DNA hybrids shows that introns are spliced out during pre-mRNA processing. (a) Diagram of the EcoRI A fragment of adenovirus DNA, which extends from the left end of the genome to just before the end of the final exon of the hexon gene. The gene consists of three short exons and one long (~ 3.5 kb) exon separated by three introns of ~ 1, 2.5, and 9 kb. (b) Electron micrograph *(left)* and schematic drawing *(right)* of a hybrid between an EcoRI A DNA fragment and a hexon mRNA. The loops marked A, B, and C correspond to the introns indicated in (a). Since these intron sequences in the viral genomic DNA are not present in the mature hexon mRNA, they loop out between the exon sequences that hybridize to their complementary sequences in the mRNA. (c) Consensus sequences around splice sites in vertebrate pre-mRNAs. The only nearly invariant bases are the $5'$ GU and the $3'$ AG of the intron (blue), although the flanking bases indicated are found at frequencies higher than expected based on a random distribution. A pyrimidine-rich region (hatch marked) near the $3'$ end of the intron is found in most cases. The branchpoint A, also invariant, usually is 20–50 bases from the $3'$ splice site. The central region of the intron, which may range from 40 bases to 50 kilobases in length, generally is unnecessary for splicing to occur. See R. A. Padgett et al.,

1986, *Ann. Rev. Biochem.* **55**:1119, and E. B. Keller and W. A. Noon, 1984, *Proc. Nat'l. Acad. Sci. USA* **81**:7417.

[Micrograph in (b) Data from S. M. Berget et al., 1977, *Proc. Nat'l. Acad. Sci. USA* **74**:3171;]

The location of *splice sites* — that is, exon-intron junctions — in a pre-mRNA can be determined by comparing the sequence of genomic DNA with that of the cDNA prepared from the corresponding mRNA (see Figure 6-17). Sequences that are present in the genomic DNA but absent from the cDNA represent introns and indicate the positions of splice sites. Such analysis of a large number of different mRNAs revealed moderately conserved, short consensus sequences at the splice sites flanking introns in vertebrate pre-mRNAs; a pyrimidine-rich region just upstream of the 3′ splice site is also common (Figure 9-7c). Studies of mutant genes with deletions introduced into introns showed that much of the central portion of introns can be removed without affecting splicing; generally, only 30–40 nucleotides at each end of an intron are necessary for splicing to occur at normal rates.

Analysis of the intermediates formed during splicing of pre-mRNAs in vitro led to the discovery that splicing of exons proceeds via two sequential *transesterification reactions* (Figure 9-8). Introns are removed as a lariat structure in which the 5′ G of the intron is joined in an unusual 2′,5′-phosphodiester bond to an adenosine near the 3′ end of the intron. This adenosine (A) residue is called the *branch-point A* because it forms an RNA branch in the lariat structure. In

each transesterification reaction, one phosphoester bond is exchanged for another. Since the number of phosphoester bonds in the molecule is not changed in either transesterification reaction, no energy is consumed. The net result of these two reactions is that two exons are ligated and the intervening intron is released as a branched lariat structure.

FIGURE 9-8 Two transesterification reactions that result in splicing of exons in pre-mRNA. In the first reaction, the ester bond between the 5′ phosphorus of the intron and the 3′ oxygen (dark red) of exon 1 is exchanged for an ester bond with the 2′ oxygen (blue) of the branch-site A residue. In the second reaction, the ester bond between the 5′ phosphorus of exon 2 and the 3′ oxygen (orange) of the intron is exchanged for an ester bond with the 3′ oxygen of exon 1, releasing the intron as a lariat structure and joining the two exons. Arrows show where activated hydroxyl oxygens react with phosphorus atoms.

During Splicing, snRNAs Base-Pair with Pre-mRNA to Select Splice Sites and Guide the Transesterification Reactions

Splicing requires highly abundant **small nuclear RNAs (snRNAs)**, important for base pairing and other interactions with the pre-mRNA, as well as ∼150 splicing factor proteins. Five U-rich snRNAs restricted to the nucleus, designated *U1, U2, U4, U5*, and *U6*, participate in pre-mRNA splicing. Ranging in length from 107–210 nucleotides in vertebrates, these snRNAs are associated with 5–12 proteins each in the abundant small nuclear ribonucleoprotein particles (snRNPs) in the nuclei of eukaryotic cells (see Figure 9-10).

Definitive evidence for the function of U1 snRNA in splicing came from experiments indicating that base pairing between the 5′ splice site of a pre-mRNA and the 5′ region of U1 snRNA (Figure 9-9a) is

required for RNA splicing (Figure 9-9b). In vitro experiments showed that a synthetic oligonucleotide that hybridizes with the 5′-end region of U1 snRNA blocks RNA splicing. In vivo experiments showed that base pairing–disrupting mutations in the pre-mRNA 5′ splice site (red A in Figure 9-9b, *left*) also block RNA splicing; in this case, however, splicing can be restored by expression of a mutant U1 snRNA with a *compensating mutation* (red U in Figure 9-9b) that restores base pairing to the mutant pre-mRNA 5′ splice site. These results and similar experiments with other mutations in pre-mRNA bases near a 5′ splice site and compensating mutations in U1 snRNA that restore base pairing to the mutant pre-mRNA, showed that, except for the invariant GU at the 5′ end of nearly all introns, base pairing with the U1 5′ region, rather than a specific RNA sequence, is required for RNA splicing.

FIGURE 9-9 Base pairing between pre-mRNA, U1 snRNA, and U2 snRNA early in the splicing process. (a) In this diagram, secondary structures in the snRNAs that are not altered during splicing are depicted schematically. The rectangles labeled Sm are binding sites for a ring of seven Sm proteins that encircle the snRNA at the positions shown in U1 and U2 snRNAs. The same Sm proteins also form a ring around U4 and U5 snRNAs (not shown). The invariant yeast branch-point sequence UACUAAC is shown here, with the bulged branch-point A indicated. Note that U2 snRNA base-pairs with a sequence that includes the branch-point A, although the branch-point A is not base-paired. (b) Only the 5′ ends of U1 snRNAs and 5′ splice sites in pre-mRNAs are shown. *Left:* A mutation (red A) in a pre-mRNA splice site that interferes with base pairing to the 5′ end of U1 snRNA blocks splicing. *Right:* Expression of a U1 snRNA with a compensating mutation (red U) that restores base pairing also restores splicing of the mutant pre-mRNA. (c, d) Structure of a bulged A in an RNA-RNA helix, as in the pre-mRNA branch-point A base paired to U2 snRNA in (a). The structure of an RNA duplex with the sequence shown (c), containing bulged A residues (red) at position 5 in the RNA helix, was determined by x-ray crystallography (d). The bulged A residues extend from the side of an A-form RNA-RNA helix. The phosphate backbone of one strand is shown in green;

the other strand in blue. The structure on the right is turned 90° for a view down the axis of the helix. See M. J. Moore et al., 1993, in R. Gesteland and J. Atkins, eds., *The RNA World*, Cold Spring Harbor Press, pp. 303–357. See also Y. Zhuang and A. M. Weiner, 1986, *Cell* **46**:827.

[Parts (c) and (d) Data from J. A. Berglund et al., 2001, *RNA* **7**:682.]

Involvement of U2 snRNA in splicing was initially suspected when it similarly was found to have an internal sequence that is largely complementary to the consensus sequence flanking the branch-point A in pre-mRNAs (see Figure 9-7c). Compensating mutation experiments, similar to those conducted with U1 snRNA and 5′ splice sites, demonstrated that base pairing between U2 snRNA and the branch-point sequence in pre-mRNA (see Figure 9-7c) is also critical to splicing.

Significantly, the branch-point A itself, which is not base-paired to U2 snRNA, bulges out (Figure 9-9a), allowing its 2′ hydroxyl to participate in the first transesterification reaction of RNA splicing (see Figure 9-8). The structure of a model RNA-RNA duplex with two bulged As (Figure 9-9c) was determined by x-ray crystallography, showing the structure of a bulged-out A similar to the bulged-out A generated when U2 snRNA base pairs with the branch-point region of pre-mRNA (Figure 9-9d).

Spliceosomes Catalyze Pre-mRNA Splicing

Much of our understanding of the mechanisms regulating pre-mRNA splicing has come from biochemical studies with extracts of cultured mammalian cells and yeast and from genetic studies in yeast. The two transesterification reactions of RNA splicing are catalyzed by a 1.3 megadalton RNA-protein complex called the **spliceosome**, similar in size to the small ribosomal subunit. The spliceosome is assembled using five smaller ribonucleoprotein complexes called **snRNPs (small ribonuclear particles) U1, U2, U4, U5, and U6** assembled on the snRNAs described above with the same names (Figure 9-10). (U3 RNA, discussed later, is not involved in pre-mRNA splicing; rather, it functions in pre-ribosomal RNA processing; see Figure 9-46.)

FIGURE 9-10 Structures of *Saccharomyces cerevisiae* snRNPs involved in pre-mRNA splicing. The secondary structures of the snRNAs are diagrammed at the left, and the three-dimensional structures determined by cryo-EM are shown at the right, with the locations of associated proteins indicated by ribbon diagrams. Each of the five small nuclear ribonucleoprotein particles (snRNPs) is shown with shades of distinct colors (U1, blue; U2, pink; U4, orange; U5, yellow; U6, green). "Sm site" in the RNA secondary structure diagrams of the U1, U2, U4, and U5 snRNAs are sites where a ring of seven Sm proteins encircle the snRNA. An alternative seven-protein ring composed of proteins LSM2-8 forms around the 3′ end of the U6 snRNA.

[Data from C. Plaschka, A. J. Newman, and K. Nagai, 2019, *Cold Spring Harb. Perspect. Biol*. **11**:a032391.]

The U1, U2, U4, U5, and U6 snRNPs associate *transiently* with each other and with splice sites in pre-mRNAs to assemble an active spliceosome that includes only the U2, U5, and U6 snRNPs (Figure 9-

11a). The active spliceosome also includes two large multiprotein complexes called *NTR* and *NTC* (Figure 9-11a). As can be seen from Figure 9-11b highlighting the snRNAs, the active spliceosome is composed primarily of protein. The fully assembled, active spliceosome performs the two-step splicing reaction and then dissociates. Studies of yeast temperature-sensitive mutants identified ~150 essential protein-coding genes required for RNA splicing, most of which have clear orthologs in humans. Most of these encode polypeptides that are transiently bound and then dissociate from spliceosome assembly intermediates, as well as factors released in association with the excised lariat intron. The released snRNPs and splicing-protein factors then reassemble onto another pre-mRNA splice site to catalyze another two-transesterification splicing reaction.

FIGURE 9-11 Structure of the catalytically active yeast spliceosome. (a) U5 snRNP (yellow) forms a scaffold onto which the other three major subcomplexes of the

catalytically active spliceosome (U2 snRNP (pink) and protein complexes NTR (light purple) and NTC (dark purple) dock around the RNA molecules and the catalytic center. The four RNA molecules visible in this space-filling model are colored orange for U2, yellow for U5, green for U6, and red for the intron lariot RNA. (b) Positions of U6, U5, two portions of U2 snRNAs, and the lariat intron RNA (red) in the catalytically active spliceosome, determined at high resolution by cryo-EM.

Unlike the ribosome during protein synthesis, the spliceosome is not a stable complex. During assembly of the active spliceosome, some snRNPs and additional splicing factor proteins initially associate with assembly intermediates and then are released. As discussed above, the RNA-splicing reaction results in no change in free energy since there is no change in the number of phosphodiester bonds before and after the reaction. However, during RNA splicing in the cell, the process is driven toward ligation of the 5′ and 3′ exons by RNA-helicase enzymes (proteins), utilizing energy from ATP hydrolysis, as discussed below.

In yeast, the 5′ splice site and branch-point sequences are stringently conserved for almost all introns (Figure 9-12). In contrast, splice sites and branch-point sequences are highly degenerate in mammals, except for the GU and AG at the 5′ and 3′ ends of most introns and the defining A at the branch point (Figure 9-12). This is because compared to yeast, mammals utilize multiple

additional sequence-specific RNA-binding proteins that assist and regulate snRNP U1 and U2 binding to 5′ splice sites and the branch point, respectively. This allows alternative splicing of primary transcripts in mammals by regulating the activities of these RNA-binding proteins. Comparison of the more simplified splicing system in yeast with the more complex system in mammals facilitated studies in both systems and an understanding of how additional nuclear proteins in mammals participate in and regulate alternative RNA splicing.

FIGURE 9-12 RNA sequences at the splice sites and branch-point A in yeast and humans. Yeast exhibit more conserved splice site and branch-point sequences than mammalian cells [note the high number of N's (any base) in the mammalian sequence].

Pre-mRNA Splicing Cycle

In yeast, 10 complexes of snRNPs and protein splicing factors have been distinguished during a splicing cycle (Figure 9-13). As discussed above (Figure 9-9a), spliceosome assembly initiates through base pairing interactions between the U1 snRNA in a U1

snRNP and a 5′ splice site in a pre-mRNA (Figure 9-9a, *left*). Next, in mammalian cells, a heterodimeric splicing factor protein called *U2 associated factor (U2AF)*, together with another protein factor, splicing factor 1 (SF1), promote association of a U2 snRNP with a branch-point sequence near the 3′ end of the intron (Figure 9-9a, *right*). The small U2AF subunit binds the 3′ splice site AG, and the large U2AF subunit binds the polypyrimidine tract in metazoans. SF1 interacts transiently with the branch-point A, and then is released as U2 snRNA base pairs to the branch-point region (Figure 9-9a). Together, these interactions specify the location of a 3′ splice site used in a splicing reaction. Other protein splicing factors not shown associate with and stabilize these U1 and U2 snRNA interactions with the pre-mRNA.

FIGURE 9-13 Ten complexes of pre-mRNAs with snRNPs and protein splicing factors have been distinguished during the splicing cycle in yeast. The names of each complex are indicated around the circumference of the diagram. See text for explanation.

[Data from C. Plaschka, A. J. Newman, and K. Nagai, 2019, *Cold Spring Harb. Perspect. Biol.* **11**:a032391.]

U2 snRNP association is followed by large conformational rearrangements of the snRNPs, including association of a pre-assembled *tri-snRNP complex* of U4, U5, and U6 snRNPs (Figure 9-10) during the transition from the A to pre-B complex (Figure 9-13). This

is followed by dissociation of the U1 snRNP to form the B-complex. The U4 snRNP then dissociates as the large multisubunit protein complexes NTC (composed of seven polypeptides) and NTR (composed of six polypeptides) associate, generating the B^{act} complex. The snRNP rearrangements that occur during the transition from the B complex to the B^{act} complex generate new interactions between U6 and U2 and between U6 and the 5′ splice site (Figure 9-14a) that are required for catalysis of the two splicing-transesterification reactions.

FIGURE 9-14 Rearrangements of snRNPs generate an active catalytic site. (a) The network of RNA interactions in the precatalytic B-complex (*top*) and the catalytically active B^{act} complex (*bottom*). During activation, base pairing interactions in the B complex indicated by dashed red ovals including regions in U4, U6 and U2 undergo major rearrangements. U1 and U4 snRNPs dissociate from the spliceosome, allowing the 5′ end of the U6 snRNA to base pair through its highly conserved ACAGAG motif to the 5′ splice site (dashed red oval). Other critical base-pairing interactions in the Bact complex are indicated (dashed red ovals). (b)

Structures of the RNAs in the precatalytic B-complex visualized at high resolution by cryo-EM. (c) RNA elements at the splicing active site of the Bact complex. Mg^{+2} ions are held by U6 snRNA in the correct geometry relative to the $5'$ and $3'$ splice sites and the branchpoint A and elements of U2 and U5 snRNAs to catalyze the two splicing transesterification reactions.

[Part (a) Data from M. C. Wahl, C. L. Will, and R. Luhrmann, 2009, *Cell* **136**:701–718. Part (b) Data from C. Plaschka, A. J. Newman, and K. Nagai, 2019, *Cold Spring Harb. Perspect. Biol.* **11**:a032391. Part (c) Data from C. Yan, R. Wan, and Y. Shi, 2019, *Cold Spring Harb. Perspect. Biol.* **11**:a032409.]

These rearrangements of the snRNPs and protein splicing factors generate a catalytic active site (Figure 9-14b) where the first transesterification is catalyzed, followed by the second transesterification joining the $5'$ and $3'$ exons. The two reactions take place without significant rearrangement of the active site other than the positions of the phosphoester bonds at the splice sites (distinguishing complexes B*, C, and C*; Figure 9-13). Unlike the ribosome, in which RNA accounts for $\sim$50 percent of the molecular mass, the three snRNAs (U2, U5, and U6) of the catalytically active human spliceosome represent no more than 5 percent of its total molecular mass (Figure 9-11). This seems consistent with the important functions of proteins at many steps in the splicing process. Spliceosomal protein components organize the splicing active site, deliver the reactive chemical groups into the active site, drive the reaction toward exon joining, and regulate the splicing process.

The splicing process is completed by disassembly of the spliceosome, which requires the NTC and NTR protein complexes

(Figure 9-13, complex P → ILS). This results in release of the product spliced RNA with the 5′ exon ligated to the 3′ exon by a standard 5′ to 3′ phosphodiester bond, and release of the intron lariat RNA associated with U2, U5, and U6 snRNPs, and the NTC and NTR protein complexes (labeled *ILS* in Figure 9-13 for *i*ntron *l*ariat *s*pliceosome). Degradation of the intron lariat by a debranching enzyme that cleaves the 2′–5′ phosphodiester bond with the branch-site A and by 5′ and 3′ exonucleases releases the U2, U5, and U6 snRNPs and splicing factors for use in another cycle of splicing (Figure 9-13, Recycling).

Several RNA helicases are required in the splicing process (indicated by * in Figure 9-13). For example, the RNA helicase Brr2 is required for the critical transition from the catalytically inactive B complex that contains all the snRNPs required for splicing (but in inactive conformations), to the catalytically active B^{act} complex. Many RNA helicases are proposed to break RNA-RNA base pairs by binding single-stranded RNA together with ATP next to an RNA-RNA duplex. ATP hydrolysis is then coupled to a change in the helicase conformation that pulls the single-stranded RNA through the active site of the helicase in a 3′ direction. This dislodges a complementary single strand or a protein bound to the RNA. Brr2 is postulated to bind the single-stranded U4 snRNA in the U4/U6/U5 tri-snRNP next to the U4/U6 duplex (Figure 9-10, U4/U6 stem 1) and then pull on the RNA in the 3′ direction, causing unwinding of the U4/U6 duplex and dissociation of the associated proteins. This allows U4 to be released

from the complex and U6 to change conformation in order to make interactions with the 5′ splice site and to bind two Mg^{2+} ions in the proper geometry relative to the splice sites and branch-point A to catalyze the exchange of phosphodiester bonds (Figure 9-14c). RNA is central to the catalytic mechanism. The transesterification reactions are catalyzed by the two Mg^{2+} ions bound by snRNA U6. The critical branch-site A 2′-OH is exposed through RNA-RNA interactions. However, proteins stabilize and guide these RNA-RNA interactions, and RNA helicases use energy from ATP hydrolysis to push the reaction cycle in favor of exon joining. Consequently, the spliceosome is considered to be a *protein-directed metalloribozyme*.

Exon Junction Complexes in Vertebrates

Following RNA splicing in vertebrates, a specific set of hnRNP proteins remain bound to the spliced RNA approximately 20 nucleotides 5′ to each exon-exon junction, thus forming an *exon-junction complex.* One of the hnRNP proteins associated with the exon-junction complex is the *R*NA *e*xport *f*actor (REF), which functions in the export of fully processed mRNPs from the nucleus to the cytoplasm, as will be discussed in Section 9.3. Other proteins associated with the exon-junction complex function in a quality-control mechanism that leads to the degradation of improperly spliced mRNAs, known as *nonsense-mediated decay* (Section 9.4).

Rare 5′-AU … AC-3′ Introns

A small fraction of pre-mRNAs (∼1 percent in humans) contain introns whose splice sites do not conform to the standard consensus sequence. This class of introns begins with AU and ends with AC rather than following the usual "GU-AG rule" (see Figure 9-7c). Splicing of this special class of introns occurs via a splicing cycle analogous to that shown in Figure 9-13, except that four novel, low-abundance snRNPs, together with the standard U5 snRNP, are involved.

Trans-Splicing

Nearly all functional mRNAs in vertebrate, insect, and plant cells are derived from a single molecule of the corresponding pre-mRNA by removal of internal introns and splicing of exons. However, in two types of protozoans — trypanosomes and euglenoids — mRNAs are constructed by splicing together separate RNA molecules. This process, referred to as *trans-splicing,* is also used in the synthesis of 10–15 percent of the mRNAs in the nematode (roundworm) *Caenorhabditis elegans,* an important model organism for studying embryonic development. Trans-splicing is carried out by snRNPs and splicing factors by a process similar to the splicing of exons in a single pre-mRNA (Figure 9-8), except that there is a break in the loop representing the intron.

3′ Cleavage and Polyadenylation of Pre-mRNAs Are Tightly Coupled

In eukaryotic cells, all mRNAs, except histone mRNAs, have a 3′ **poly(A) tail**. Early studies of pulse-labeled adenovirus and SV40 RNA demonstrated that the viral primary transcripts extend beyond the sequence that is polyadenylated. These results suggested that A residues are added to a 3′ hydroxyl generated by endonucleolytic cleavage of a longer transcript. But the predicted downstream RNA fragments were never detected in vivo, presumably because of their rapid degradation. However, detection of both predicted cleavage products was observed in the in vitro processing reactions performed with nuclear extracts of cultured human cells. The cleavage/polyadenylation process and degradation of the RNA downstream of the cleavage site occurs much more slowly in these in vitro reactions, simplifying detection of the downstream cleavage product.

Early sequencing of cDNA clones from animal cells showed that nearly all mRNAs contain the sequence AAUAAA 10–35 nucleotides *upstream* from the poly(A) tail (Figure 9-15). Polyadenylation of RNA transcripts is virtually eliminated when the corresponding sequence in the template DNA is mutated to any other sequence, except the closely related sequence (AUUAAA). The unprocessed RNA transcripts produced from such mutant templates do not accumulate in nuclei but are rapidly degraded. Further mutagenesis

studies revealed that a second signal downstream from the cleavage site is required for efficient cleavage and polyadenylation of most pre-mRNAs in animal cells. This downstream signal is not a specific sequence but rather a GU-rich or simply a U-rich region within ~20 nucleotides of the cleavage site.

FIGURE 9-15 Model for cleavage and polyadenylation of pre-mRNAs in mammalian cells. Cleavage and polyadenylation specificity factor (CPSF) binds to the upstream AAUAAA poly(A) signal. CStF interacts with a downstream GU- or U-rich sequence and with bound CPSF, forming a loop in the RNA; binding of CFI and CFII helps stabilize the complex. Binding of poly(A) polymerase (PAP) then stimulates cleavage at a poly(A) site, which usually is 10–35 nucleotides $3'$ of the upstream poly(A) signal. The cleavage factors are released, as is the downstream RNA cleavage product, which is rapidly degraded. Bound PAP then adds ~ 12 A residues at a slow rate to the $3'$-hydroxyl group generated by the cleavage reaction. Binding of poly(A)-binding protein (PABPNI) to the initial short poly(A) tail accelerates the rate of addition by PAP. After 200–250 A residues have been added, PABPN1 signals PAP to stop polymerization.

Purification of the proteins required for cleavage and polyadenylation of pre-mRNA precursors in vitro led to the initial identification of proteins involved in the process. This was followed by isolation and sequencing of the genes encoding them, purification of the recombinant proteins expressed from these genes, and then further identification of associated proteins by binding to the overexpressed proteins and by co-purification of epitope-tagged versions of the proteins expressed in vivo. Studies

with these purified proteins led to the model of cleavage and polyadenylation in Figure 9-15.

In *S. cerevisiae*, 14 or 15 polypeptides assemble into an ∼1 million Dalton complex with three modules that perform cleavage and polyadenylation at the poly(A) site. One module binds the AAUAAA RNA sequence in the pre-mRNA and cleaves the RNA 10–35 bases downstream. The variation in distance may be due to different secondary structures in the RNA between the AAUAAA and the cleavage site for each pre-mRNA. The second module of the cleavage polyadenylation complex includes two phosphatases that appear to regulate elongation by RNA polymerase II and polyadenylation. The third module includes the poly(A) polymerase enzyme that adds A's to the 3′ end of the RNA generated when the first module cleaves downstream of AAUAAA sequence.

Following cleavage at the poly(A) site, polyadenylation proceeds in two phases. Addition of the first 12 or so A residues occurs slowly, followed by rapid addition of up to 200–250 more A residues. The rapid phase requires the binding of multiple copies of a *poly(A)-binding protein* containing an RRM motif. This protein is designated *PABPNI* to distinguish it from the poly(A)-binding proteins present in the cytoplasm (*PABPC1,2,3*). PABPN1 binds to the short A tail initially added by PAP, stimulating the rate of polymerization of additional A residues by PAP, resulting in a much faster phase of polyadenylation. PABPN1 is also responsible for signaling poly(A)

polymerase to terminate polymerization when the poly(A) tail reaches a length of 200–250 residues, although the mechanism for controlling the length of the tail is not yet understood. Binding of PABPN1 to the poly(A) tail is essential for mRNA export into the cytoplasm where it is replaced by a PABC1, 2, or 3 and shuttled back into the nucleus.

Alternative Polyadenylation Sites

In addition to alternative splicing, mRNA regulation is also mediated by *alternative polyadenylation,* which occurs for ~50 percent of human mRNAs. Alternative polyadenylation results from the use of two or more alternative cleavage/polyadenylation signals in alternative cell types. In some cases, this appears to be due to different concentrations of the polyadenylation factors in alternative cell types coupled with alternative poly(A) sites that have higher or lower affinity for the cleavage polyadenylation complex that binds the downstream G/U-rich portion of the cleavage/polyadenylation signal (Figure 9-15). In these cases, when the concentration of the factor is low, only the highest affinity cleavage/polyadenylation sites are used. But in alternative cell types where the factor concentration is higher, an upstream low-affinity site is used preferentially because it is bound by the cleavage/polyadenylation factor at the higher concentration, and once the pre-mRNA is cleaved, the downstream site cannot be used. In other cases, sequence specific RNA-binding proteins may block or enhance binding of the

cleavage/polyadenylation factors, similarly to the way they regulate the binding of splicing repressors and activators.

Alternative sites of polyadenylation can also be coupled to alternative splicing of the final exon in an mRNA. As a consequence, protein isoforms can be expressed that have alternative C-terminal amino acid sequences. This is observed in the expression of alternative immunoglobulin molecules during B-lymphocyte development (see Figure 24-19). Initially, an antibody is produced with a transmembrane domain that anchors the antibody in the plasma membrane, and a cytoplasmic domain that signals when the antigen-binding extracellular domain encounters antigen — the molecule bound by an antibody. When that occurs, processing of the pre-mRNA is modified so that an alternative 3′ exon is included in the mRNA. The resulting antibody molecules translated from this alternatively processed mRNA lack the membrane-spanning domain and, as a consequence, are secreted into the extracellular space where they can neutralize pathogens (see Chapters 14 and 24).

RNA Polymerase II Transcription Termination

Pol II generally terminates transcription at any one of several alternative sites within ~2 kb of the poly(A) site. Experiments with SV40 and adenovirus, both DNA viruses, showed that when the polyadenylation signal is mutated, RNA polymerase does not terminate transcription but continues transcription until the next

poly(A) site in the viral genome is encountered. Similar results were observed when a wild-type copy of the β-globin gene was inserted downstream of a viral promoter in the genome of a DNA virus. These experiments showed that transcription termination by RNA polymerase II is coupled to cleavage and polyadenylation of the transcript, and that the RNA fragment downstream of the cleavage site is rapidly degraded. This is thought to be due to the de-protection of the $5'$ end of the nascent transcript. Because no cap is present on the $5'$ end of the cleaved RNA, it is susceptible to digestion by the major $5' \rightarrow 3'$ exoribonuclease in the nucleus, *XRN1*. It is thought that when XRN1 reaches the still transcribing polymerase, it triggers termination, either by pulling the $3'$ end of the nascent RNA out of the polymerase active site, or by introducing a conformational change in the polymerase that causes transcription termination. Once the nascent RNA is removed from the elongating polymerase, the contacts between the RNA polymerase II clamp and the RNA-DNA hybrid within the polymerase (see Figure 8-9b) are lost, allowing the clamp to swing open and release the polymerase from the DNA template.

KEY CONCEPTS OF SECTION 9.1

Processing of Eukaryotic Pre-mRNA

- In the nucleus of eukaryotic cells, pre-mRNAs are associated with hnRNP proteins and processed by $5'$ capping, $3'$ cleavage/polyadenylation, and RNA splicing to remove internal introns before being transported to the cytoplasm (see Figure 9-2).

- In multicellular organisms, splicing of exons in long genes with multiple exons usually begins as the pre-mRNA is still being transcribed. Cleavage and polyadenylation to form the $3'$ end of the mRNA occur after the poly(A) site is transcribed.
- Transcription and RNA processing are coupled via the carboxy-terminal domain (CTD) of RNA polymerase II. $5'$-capping enzymes interact with the CTD phosphorylated at Ser-5 by TFIIH during transcription initiation. The $5'$ cap protects the nascent pre-mRNA from $5'$exonucleases.
- Factors involved in RNA splicing and $3'$ cleavage and polyadenylation associate with the Pol II CTD phosphorylated on Ser-2 by cyclin T-CDK9 during release of the paused polymerase early in gene transcription (Figures 8-13a, 8-16). These interactions with the phosphorylated CTD allow the processing factors to interact with the nascent pre-mRNA shortly after it emerges from the surface of the polymerase.
- Splicing occurs at short, conserved *splice sites* in pre-mRNAs (Figure 9-7c), via two transesterification reactions (Figure 9-8). The first of these generates a *lariat intron* with an unusual $2'$-$5'$ phosphoester bond at the *branch-point A*.
- Five different abundant *small nuclear RNAs (snRNAs)* are found in snRNA-protein complexes (*snRNPs*). These interact via base pairing of their snRNAs with one another and with pre-mRNA to form the 1.3 MDa spliceosome (see Figure 9-11).
- Multiple specific proteins are also associated with the catalytically active spliceosome, comprising 95 percent of its mass (Figure 9-11b).
- The spliceosome is not a stable complex. During assembly of the active spliceosome, some snRNPs and additional splicing factor proteins initially associate with assembly intermediates, and then are released.
